Abstract
Occurrence of solitary intramuscular cysticercosis without involvement of the central nervous system is rare. We report a case of solitary cysticercosis of the brachioradialis muscle in a 35-year-old woman who presented with discomfort and pain in the right elbow and arm after trivial trauma. There were no systemic or neurological features.

Keywords: Intramuscular cysticercosis, magnetic resonance imaging, solitary

Case Report
A 35-year-old woman had hurt her elbow and upper arm in a fall at home about a week back. X-rays of the arm and the forearm were normal with no evidence of fracture or dislocation. Her clinical examination was also normal. She was given oral analgesic medication, but there was no improvement in the pain and discomfort. Subsequently she underwent magnetic resonance imaging (MRI), which revealed small oval cystic foci of T1-hypointensity measuring $12 \times 10$ mm in size in the right brachioradialis muscle [black arrow in Figure 1]. It was found to be oriented along the direction of the muscle fibers. A small T1-hyperintense eccentric focus was noted within the cystic lesion, representing the scolex [solid white arrow in Figure 1].

Perilesional muscles and fat planes were normal. Ipsilateral distal humerus, radius, and ulna showed normal cortical and marrow substances. These imaging findings were diagnostic of intramuscular cysticercosis.

The patient was put on oral albendazole (15 mg/kg) for 4 weeks. After completion of the treatment, the pain and discomfort had completely subsided. Follow-up ultrasound of the right arm showed no residual lesion.

Discussion
Cysticercosis is no longer a disease of the third world, but it is increasingly being reported from the devolved world due to influx of immigrants. The encysted larva can lodge in the nervous system, subcutaneous tissues, eyes, viscera, muscles, and many other organs of the human body. Most of the skin and intramuscular lesions coexist with central nervous system involvement.
Solitary cysticercosis of muscle without involvement of the central nervous system is a rare entity and a few case reports have been reported in the literature.\(^{1,2}\) These solitary presentations of cysticerci are confusing as they present with vague misleading symptoms and there are no pathognomonic clinical symptoms. In such difficult clinical scenarios, radiology-based investigations such as ultrasound and MRI play a pivotal role in diagnosis. The differential of solitary cysticercosis of the muscle should always be considered in the clinical scenario of intractable pains of the limbs.
