Abstract

Background: Optimal management of asthma in resource limited settings is hindered by lack of resources, making it difficult for health providers to adhere to international guidelines. The purpose of this review is to identify steps for asthma diagnosis and management in resource limited settings.

Methods: Review of international asthma guidelines and other published studies on diagnosis and management of asthma.

Results: We establish that clinical diagnosis of asthma can be made if recurrent respiratory symptoms especially current wheeze or wheeze in the last 12 months are present. Presence of a trigger, other allergic diseases, personal or family history of asthma; clinical improvement and increase in the peak flow and forced expiratory volume in one second of ≥12% after salbutamol administration increases the likelihood of asthma. At diagnosis severity grading, patient education, removal or reduction of trigger should be done. Follow up 2-6 weeks and assessment of control during therapy is essential. Therapy should be adjusted up or down depending on control levels. Patients should be instructed to increase the frequency of their bronchodilators and/or steroids therapy when they start to experience worsening symptoms.

Conclusion: Good quality asthma care can be achieved in resource limited settings by use of clinical data and simple tests.

Keywords: Asthma, diagnosis, treatment, management and resource limited settings.

Case scenario

“A 24-year-old woman presents with shortness of breath, wheezing especially at night for four weeks. She has had to stop her job of hawking fruits on the streets because of these symptoms. Her symptoms are worsened by cold weather, wood smoke and dust. There are cockroaches in her house but she says these do not cause her any problems.

Prior to the onset of these problems, she had never had any illness similar to this but reports recurrent nasal blockage and sneezing in the morning and evening since childhood. Her mother had asthma all her life and her 1 year old baby has prolonged and recurrent attacks of cough. She has no other medical problems and her last normal menstrual period was two weeks ago.

Peak expiratory flow rate (PEFR) measurements are 200ml/min and 320ml/min before and after administration of salbutamol. Part of her spirometry results are as follows: pre-bronchodilator FEV1 = 2.8L (63% predicted) and post-bronchodilator FEV1 = 3.18 (84% predicted).

Introduction

Asthma is a common chronic disorder of the airways that is characterized by variable and recurring symptoms, airflow obstruction, bronchial hyper-responsiveness, and an underlying inflammatory process. Global prevalence of asthma is estimated at 10-20% of adults. In Uganda, a retrospective chart review found that one in six patients receiving care at the Mulago hospital chest clinic had asthma.
Asthma management should follow standardized guidelines in order to optimize outcomes. This is however often not easily achieved in resource limited settings (RLS). Firstly, in many cases no national asthma guidelines are present. Secondly, due to the limited range of diagnostics and pharmaceuticals present in these countries and the high cost of chronic disease management, the already present international guidelines, that require these diagnostics and pharmaceuticals, cannot be easily adapted to local circumstances. As a result, there is great variability in asthma management in RLS. We have performed a critical review of the international asthma guidelines and describe a simple step-by-step process of diagnosing and managing asthma in RLS.

**Clinical diagnosis of asthma**

Patients presenting with recurrent symptoms of wheeze, breathlessness, cough (especially at night/morning and/or with exercise) and chest tightness should be evaluated for asthma.\(^2,4-8\). Presence of a specific trigger, other allergic diseases such as allergic rhinitis, a history of improvement of symptoms following past use of bronchodilator drugs (commonly salbutamol), personal or family history of asthma increase the likelihood of asthma.\(^2,4,9\)

Clinicians should always gather information regarding history of wheeze, even if the patient does not spontaneously mention this. It must be noted that equivalent words for wheeze may not exist in common language. Therefore, healthcare workers (HCWs) should use locally appropriate illustrative phrases and examples to be able to obtain an accurate history of wheeze. Wheezing auscultated on chest examination further increases the possibility of an asthma diagnosis. If a wheeze is not present on normal quiet breathing, ask the patient to forcefully exhale, this may make the wheeze audible. HCWs should however be aware that in severe forms of asthma, the chest may be silent i.e. no breath sounds at all and no wheeze.

**Asthma diagnostic tests**

The commonly available tests for asthma in RLS are the peak expiratory flow rate (PEFR) and spirometry. Both PEFR and spirometry are performed to demonstrate reversible airflow obstruction, the hallmark physiological derangement in asthma.

The PEFR meter measures the maximum flow rate generated during a forceful exhalation starting from full lung inflation (peak flow). On the other hand spirometry also measures peak flow but also measures other lung ventilation parameters such as how much of the air is expelled in the first one second (FEV\(_1\)) and the total amount of air that can be forcefully exhaled from the lungs after a full inspiration (forced vital capacity, FVC). It is more accurate and gives reproducible results than the PEFR meter.\(^2\)

The first step is to demonstrate airflow obstruction. Airflow obstruction on a PEFR meter is present when the patient’s PEFR is less than his/her predicted flow according to age, sex, and height or his/her personal best for those with previous measurements (Fig 1).\(^10\)
A short acting bronchodilator is administered and the PEFR is repeated after 15 minutes. An increase of 60ml or 20% in the PEFR represents reversible airflow obstruction. It must be noted however that PEFR is currently not recommended for asthma diagnosis by most international guidelines. However, PEFR provides additional objective evidence of airflow obstruction in the absence of spirometry.

When spirometry testing is done; the patient is tested to determine if the ratio of forced expiratory volume in the first second (FEV₁) to forced vital capacity (FVC) is less than 0.70 (or less than the lower limit of normal (LLN)). After 10-15 minutes two doses of a short acting bronchodilator, separated by one minute, are administered. If there is an improvement in FEV₁ of more than 12% and 200ml, then reversible airflow obstruction is present.

If spirometry is available it should be prioritized for diagnosis and monitoring done using the PEFR measurement in order to reduce costs. Other asthma tests include the provocation tests to demonstrate airway hyper responsiveness, allergy testing and fraction of exhaled Nitric oxide (FeNO) to demonstrate airway inflammation.

Differential diagnosis
HCWs should remember that symptoms and signs described above can occur in disease states other than asthma. Other diseases with asthma-like symptoms to consider before establishing diagnosis of asthma include: chronic obstructive pulmonary disease (COPD), hyperventilation syndrome, congestive heart failure, pulmonary embolism, mechanical obstruction of the airways (such as occurs in tumours of the lung), vocal cord dysfunction and cough secondary to drugs.
The possibility of a chronic respiratory infection such as tuberculosis (TB) should always be considered in high TB prevalence settings. We usually obtain sputum microscopy for TB and a chest x-ray as part of initial asthma work up to avoid missing a diagnosis of TB.

Classification of asthma severity and control level
A diagnosis of asthma is incomplete without grading of the severity and control of the asthma because treatment choices at the time of diagnosis and during follow up depend on the severity and control levels. Severity grading involves assessing the frequency of the asthma symptoms, physical activity limitation and frequency of using reliever or rescue medications over the past 2-4 weeks. Frequency of exacerbations and results of PEFR and spirometry tests are also used (Table 1).

Asthma severity is classified as intermittent or persistent. Patients with intermittent asthma have a) infrequent asthma symptoms usually less than 2 days per week, b) wake up because of asthma symptoms less than two times a month, and c) experience symptoms requiring rescue medication less than 2 days per week. In addition they have no interference with their physical activity because of asthma; their PEFR and/or spirometry tests results are normal and report either no/ or at most one asthma exacerbation requiring oral systemic glucocorticoids in the previous year. Persistent asthma is characterized by presence of any one of the features of moderate or severe persistent asthma that is sufficient for classification of moderate and severe persistent asthma, respectively.

Asthma control is defined as the extent to which the various manifestations of asthma are reduced or re-

moved by treatment. There are a number of questionnaires that have been designed to assess asthma control but the asthma control test (ACT) is more likely to be easily used in resource limited settings because of its simplicity and no need for tests (Table 2).

**Total Score**

Assess asthma control:

- Controlled asthma (ACT >19)
- Partly controlled asthma (ACT ≥15 and ≤19)
- Uncontrolled asthma (ACT <15)
We recently evaluated the feasibility of using the ACT in our clinic in Uganda in 120 asthma patients attending the Mulago hospital chest clinic and found it to be accurate and feasible. Controlled patients should be reviewed at 3 months intervals.

The use of the ACT involves asking patients to rate to what extent their asthma symptoms limited their activity, how often they experienced wheezing and how frequent they used reliever medications. They are also asked to rate the frequency of night symptoms and finally to rate their overall control. On basis of the scores obtained, patients are then classified as either controlled asthma (ACT > 19) or inadequately controlled asthma (ACT ≤ 19). Among those with inadequately controlled asthma 2 categories are considered: partly controlled asthma (ACT ≥15 and ≤19) and uncontrolled asthma (ACT < 15). The lowest ACT score is 5 and the highest 25.

Asthma management

Patient education and trigger avoidance

Because asthma is a chronic disease, patients should be educated to understand the nature of their illness with a focus on common asthma triggers, warning signs of exacerbations (attacks) and the commonly used asthma drugs and inhaler techniques. Patients should contemplate what their asthma trigger might be and once identified they should be assisted to work towards the reduction or removal of the trigger. Common triggers include: cockroaches, fur/haired animals like cats and dogs, pollen, molds, domestic mites, indoor and outdoor pollutants, viral infections, drugs such as non-cardio-selective beta blockers, ACE inhibitors, aspirin and other non-steroidal anti-inflammatory drugs.

Patients with asthma should be educated about other diseases that worsen asthma especially allergic rhinitis. In one study at Mulago hospital assessing the level of asthma control, presence of rhinitis symptoms was associated with a 5 fold increase in poor asthma control.

Asthma drug therapy

Asthma drugs are classified as either relievers or controllers or more broadly as either bronchodilator or anti-inflammatory drugs (Table 3).

*Modified from National Asthma Education and Prevention Program Expert Panel Report 3*
Reliever asthma drugs are bronchodilators that act fast usually within the first few minutes. For short acting beta agonists (SABA) (Salbutamol and Levalbuterol) the onset of action can be expected within 5 minutes, peaking at 30-60 minutes and lasts 4-6 hours.\textsuperscript{24,25} Because of this rapid onset of action, these drugs are used in the treatment of acute relief of acute asthma symptoms. Ipratropium is another reliever medication with a different mechanism of action. Ipratropium is a short acting anticholinergic agent (onset of action can be expected within 30-40 minutes) which can be used in combination with salbutamol.\textsuperscript{23,26-28} Adrenaline (epinephrine), an injectable short acting non selective $\beta$-agonist has been used in the past for management of acute asthma and is still listed on the WHO essential medicines list.\textsuperscript{29} It is no longer recommended for use unless no alternative is available in an emergency situation. Short acting theophylline such as aminophylline may be used for quick relief of symptoms if SABAs are not available.\textsuperscript{29} Long acting beta agonists (LABA) are bronchodilators that usually have a slow onset of action but with a long duration of action. Examples LABAs include Salmetrol and Formeterol. LABAs usually come in combination with ICS as combination inhalers. These combination inhalers are not on the WHO essential medicine list but are increasingly becoming available in RLS as generics.\textsuperscript{5}

Controller medications are the main stay of asthma management because they target the underlying inflammatory process.\textsuperscript{30,31} Controller drugs include corticosteroids, Leukotriene modifiers and anti-Immunoglobulin E therapy.\textsuperscript{2,4}

Corticosteroids (CS) are available in systemic (tablet, solution for injection) and inhalation forms. Although WHO recommends only beclomethasone and budesonide, fluticasone is also currently available. Inhaled corticosteroids (ICS) are available in low dose, medium dose and high dose inhalers.\textsuperscript{5} Classification of the inhaler as low, medium or high dose depends on the amount of ICS per dose/puff of the inhaler. For beclomethasone and fluticasone, low dose is usually up to 250mcg/dose/puff, medium dose is up 500mcg and high dose is 500mcg or more. When considering Budesonide low dose is up to 400mcg, medium dose is up 800mcg while high dose is 800mcg and above.\textsuperscript{32} HCWs should familiarize with these doses because different asthma severity grades require different ICS dose even of the same inhaler.

Systemic steroids commonly used in the management of asthma include prednisolone, hydrocortisone, and methyl prednisolone. Other controller drugs include leukotriene modifiers such as montelukast and zafirlukast and theophylline drugs such as aminophylline.\textsuperscript{35} Because theophylline drugs increase CS sensitivity their use in combination with CS may have additive clinical benefits.\textsuperscript{35} There is no role for routine antibiotics in the management of asthma. In many RLS HCWs usually prescribe antibiotics for asthma patients.\textsuperscript{3,36,37} In one study in Uganda almost half of asthma patients were prescribed antibiotics.\textsuperscript{3}

\textbf{How to initiate asthma drugs}

Before initiating asthma drugs a firm diagnosis of asthma must be made. Asthma severity or level of control must also be assessed. Drugs are then initiated and stepped up or down until asthma is brought under control (Table 4):

\begin{table}
\centering
\caption{Assessing asthma control and adjusting therapy in youths >12 years of age and adults.\textsuperscript{1,8}}

1195

\textbf{African Health Sciences Vol 15 Issue 4, December 2015}
Step 1 (Intermittent asthma): Initiate treatment at step 1: SABA inhaler to use as needed. HCWs should however note that patients who have seasonal asthma, asthma in which the trigger may not be removed easily or in the short term, those who have had more than two exacerbations in the previous year should be managed as persistent asthma until the trigger or season is over.

Step 2 (Mild persistent asthma): Initiate daily low dose ICS such as beclomethasone and as-needed SABA. Alternative to ICS include leukotriene receptor antagonists or sustained release theophylline.

Step 3 (Moderate persistent asthma): In addition to as-needed SABA plus daily low dose ICS used in Step 2, addition of LABA is recommended preferably as an ICS/LABA combination inhaler. HCWs should note that LABAs should never be used as when not in combination with ICS for asthma treatment because of progressive airway remodeling, increased risk of exacerbations and death.\(^7,38\)

Step 4 (Severe persistent asthma): As in step 3 but use medium dose ICS.

Step 5: High dose ICS plus a LABA: International guidelines recommend use of a biologic agent; omalizumab in patients in whom an allergen has been identified. This drug is far too costly to be used in RLS. We tend to add oral steroids for patients in this group.

Step 6: Patients in this group will require daily oral steroids until control is achieved.

Once treatment is initiated the patient should be followed over 2-6 weeks to assess control using the ACT.\(^2\) Controlled patients should be reviewed at scheduled intervals ranging from 3 months to a year. Controlled patients can have their treatments stepped down to suite their asthma severity. Before stepping up or down therapy it is advisable to always check whether the diagnosis of asthma is correct, inhaler technique is correct, presence of perpetuating factors (triggers) that may not have been addressed and presence of a comorbid condition that may be aggravating asthma symptoms.\(^2\)

</table>
| Mild                                                 | PEF ≥70 percent predicted or personal best | • Usually cared for at home  
• Prompt relief with inhaled SABA  
• Possible short course of oral systemic corticosteroids |
| Moderate                                              | PEF 40–69 percent predicted or personal best  
Breathless interferes with or limits usual activity | • Usually requires office or ED visit  
• Relief from frequent inhaled SABA  
• Oral systemic corticosteroids; some symptoms last for 1–2 days after treatment is begun |
| Severe                                                | PEF <40 percent predicted or personal best  
Breathless at rest; interferes with conversation | • Usually requires ED visit and likely hospitalization  
• Partial relief from frequent inhaled SABA  
• Oral systemic corticosteroids; some symptoms last for >3 days after treatment is begun  
• Adjunctive therapies are helpful |
| Subset: Life threatening                              | PEF <25 percent predicted or personal best  
Too Breathless to speak; perspiring                   | • Requires ED/hospitalization; possible ICU  
• Minimal or no relief from frequent inhaled SABA  
• Intravenous corticosteroids  
• Adjunctive therapies are helpful |

Key: ED, emergency department; FEV\(_1\), forced expiratory volume in 1 second; ICU, intensive care unit; PEF, peak expiratory flow; SABA, short-acting beta-agonist.

Indication of presence of an asthma exacerbation can be obtained from the history of progressive increase in shortness of breath, chest tightness, cough, wheezing or a combination of these symptoms. Objective evidence of worsening asthma can be obtained by documenting decreases in expiratory flow (PEFR or FEV₁) by the HCW. Patients should be educated about recognizing worsening symptoms and to increase the frequency of their reliever inhalers immediately and to seek medical attention. There is emerging evidence that quadrupling of the ICS as soon as patients realize increase in their symptoms may help avert an impending exacerbation.

All patients with asthma exacerbations should receive a course of systemic (preferably oral) of CS. Commonly we use 30-40mg of prednisolone. Mild to moderate exacerbation can be managed by repeated administration of SABA 2-4 puffs every 20 minutes for 1 hour followed by 2-4 puffs every 3-4 hours. Use of a spacer or valve holding chamber improves drug delivery and should be used whenever available. Moderate exacerbations require 6-10 puffs every 1-2 hours after the initial 1 hour.

Once there is sufficient improvement in clinical parameters and the PEFR or FEV₁ has been increased back to >80% predicted, patients can be monitored for 3-4 hours and if the response is maintained they can then be discharged. A short course of oral steroids can be initiated while the patient is still in the health facility for about 5-7 days in patients with moderate exacerbation.

When available, severe exacerbations should be managed with nebulized SABA 2.5- 5mg diluted to 3ml with normal saline every 20 minutes for 1 hour and then as needed until there is improvement. Whenever possible, oxygenation should be monitored by pulse oximetry in patients with moderate to severe exacerbations. Supplemental oxygen should be administered to achieve an SPO₂ of >90%. Systemic oral steroids should also be administered during hospitalization and continued after discharge for 5-7 days. Ipratropium may be added to the nebulization chamber along with salbutamol because this has been found to lead to better improvement than salbutamol nebulization alone. An alternative for facilities where nebulization cannot be done is use of intravenous theophylline and frequent SABA inhaler use. It must be noted that use aminophylline is not currently recommended because of lack additional benefit after administration of inhaled beta agonist and due to increased side effects.

Epinephrine (adrenaline) is still listed as an essential asthma medicine on the WHO essential medicines list. Adrenaline has a major role in patients with airway obstruction due to angioedema and other anaphylaxis situation but offers no additional benefit when SABAs have been administered as described. Its use should be discouraged.

**Back to the case scenario**

The patient presented had classical recurrent asthma symptoms. She has history of other allergic diseases (allergic rhinitis). Although she has no personal history of asthma, she has a strong family history of asthma. Triggers (dust, cold weather and smoke) were identified.

The patient's PEFR and FEV₁ are both below her predicted normal values and increase by greater than 12% following bronchodilator administration. Therefore this patient most likely has asthma. Reported daily symptoms, limited physical activity, and moderate airflow obstruction as evidenced by her PEFR and FEV₁, places this patient in the moderate persistent asthma. ACT should be administered and counselling should be done to reduce exposure to the triggers. Low dose ICS should be initiated as well as a LABA inhaler. As needed inhaled SABA should also be maintained for use when the patient experiences asthma symptoms.

Exercise related breathlessness can be prevented by taking 2 doses of inhaled salbutamol / LABA 10-15 minutes before going for her work or leukotriene modifiers such as montelukast. Starting to walk slowly and pace up can also prevent the exercise induced-breathlessness.

**Conclusion**

Although resources to adhere to international asthma guidelines are not available in most RLS good quality evidence based asthma care can be achieved if HWs consistently use clinical data, available tests, drugs and nondrug care in a step by step fashion.
