Received 2 February, 2014; Accepted 24 March, 2014

In this study, dry chicken manure (DCM) was used as the source of nitrogen in the production of *Spirulina platensis*. Experiment was conducted in two different types of nutrition. In the type I nutrition, the highest average cell increase was recorded as 289.70 filaments mL⁻¹ in value in the type I group (DCM+urea). In the type II nutrition, the highest average cell increase was recorded as 296.50 filament mL⁻¹ in value in the type II group (DCM+urea+sodium bicarbonate). In the type I nutrition (DCM+Urea), the highest specific growth rate was detected as 0.21 division day⁻¹ on the sixth day and k value as being 0.30 division day⁻¹. In the type II nutrition, the highest specific growth rate was recorded as 0.08 division day⁻¹ in the group II (DCM+Urea+NaHCO₃) and k value as being 0.12 division day⁻¹. In both types of nutrition, the protein rates of the type I group (DCM+urea) and the group III (DCM+sodium bicarbonate) are found to be higher than that in the other groups. The lipid levels in both types of nutrition, in DCM (Control) and in the type I group (DCM+Urea) were found to be higher than the other groups.

Key words: *Spirulina platensis*, dry chicken manure, sodium bicarbonate, urea.

INTRODUCTION

*Spirulina platensis* (Geitler, 1932) is a species of cyanobacteria with a commercial value. It is a species of microalgae with thread-like structure constituting intensive populations in tropic and sub-tropic waters characterized with high carbonate, bicarbonate and the highest pH value (Binaghi et al., 2003). *S. platensis* production has been launched in Turkey and has find a place in the region of nutraceuticals and pharmaceuticals fields' market (Blunden et al., 1992). *Spirulina* sp. is being used in combined feed of poultry, being an active biological additive due to high protein concentration, essential amino acids, vitamins, β-carotene, minerals, polysaccharides and essential fatty acids (Babadzhanov et al., 2004; Venkataraman et al., 1994). *Spirulina* is also stated to be a natural colorant. Hence, it is stated that it is being used in chicken eggs and fish feed; in aquaculture as natural colorant (Challem, 1981). It is also revealed that the cost can vary for the various nutrition compositions and nutrient environment for the biomass productivity of *Spirulina* sp. (Kendirli, 2010).

Microalgae are in the need of basic elements such as carbon (C), nitrogen (N) and phosphorus (P) in order to conduct the organic substance synthesis (Davis, 1977). In cultures, the most important inorganic N sources that
are able to be used by the cells are as follows: NO₃ nitrogen (NO₃-NN), NH₄ nitrogen (NH₄-N) and urea nitrogen ((NH₂)₂CO-N) (Gökpınar, 1991). *S. platensis*, as opposed to the other photosynthetic microorganisms is able to use ammonia in high pH values. The penetration of ammonia into cell for an average inner cell pH (pHᵢᵥᵥ) and the outer environment pH (pH(out)) is depended on the difference (delta pH) and limits the high pH average of inner cell. This high pH value is found to be pressured by inner thylakoid pH (Boussiba, 1989). Urea is converted to ammonia by hydrolysis in the alkaline culture media. This emerging ammonia in high concentration is able to create toxic impact for microalgae. However, addition of urea in discontinuous nutrition period enables the use of KNO₃ as the source of nitrogen in culture medium. On the other hand, it is stated that working in the industrial scale might be simpler with constant urea addition (Danesi et al., 2007).

Another way of reasonable utilization of farm manure is to use it in the production of microalgae. Nitrogen source for *S. platensis* is known to be nitrate. Furthermore, the farmers managed to produce *Spirulina* sp. using the manure disposals of pig and chicken farms as the source of nitrogen (Ungsetaphand et al., 2007). By doing so, they cut back on purchasing expensive feed additive, at the same time utilizing from the waste water, they have provided as an economic contribution (Cheunbarn et al., 2010). Algae use solar energy whilst absorbing nutrients using the carbonized substances from the waste waters in order to produce biomass. Biomass which is obtained from the useful part of the waste water ingredient is able to be used in animal feed as being a valuable nutrient source (Ratana et al., 2009). Later, researches showed that dry chicken manure provides the necessary nutrient source for *S. platensis* culture (Ungsetaphand et al., 2007).

In Turkey, the research on organic manure usage for *S. platensis* production is not yet sufficient. The aim of this study is to achieve the low cost production of *S. platensis* by adding urea and sodium bicarbonate into dry chicken manure and to determine the protein and lipid levels of the yield.

**MATERIALS AND METHODS**

*S. platensis* was produced in the Plankton Laboratory of Mersin University of Fisheries Faculty. As the culture environment *Spirulina* liquid medium was used by having been modified. NaNO₃ was not used in the modified *Spirulina* medium (Schlosser, 1982). Part I: 180.6 g NaHCO₃; 80.6 g Na₂CO₃; 10.0 g K₂HPO₄; Part II: 20.0 g K₂SO₄; 20.0 g NaCl; 4.0 g MgSO₄.7H₂O; 2.0 g CaCl₂.2H₂O; 20.0 g FeSO₄.7H₂O; 1.6 g EDTA-N₂ and 100 m, micro nutrient solution (0.001 g ZnSO₄.7H₂O; 0.002 g MnSO₄.7H₂O; 0.01 g H₂BO₃; 0.001 g Na₂MoO₄.2H₂O; 0.001 g Co(NO₃)₂.6H₂O; 0.00005 g CuSO₄.5H₂O; 0.7 g FeSO₄.7H₂O; 0.8 g EDTA-N₂). Part I and II were prepared by being added into 10 L of pure water. To constitute a inoculation culture; firstly, the cells of *Spirulina* are filtered through a 30 µm mesh net and to purify from sodium nitrate washed three times with 0.8% NaCl solution and harvested. Stabilizing the initial pH value at 10 and the temperature at 34±1°C, cells of *Spirulina* was inoculated into modified *Spirulina* medium. Initial culture was carried out by providing moderate aeration in 1 L flasks. 24 h of lighting was applied with daylight fluorescent lamps and when the culture reached to maximum intensity, the cell was inoculated into the prepared manure syrup.

In the experiment, 200 g of dry chicken manure which has been provided from a chicken farm was used for the culture medium. Dry chicken manure was powdered with a feed grinding machine and the powder sieved through 30 µm mesh net. Then, it was waited in 10 L tap water filtered through 0.45 µm membrane filter and aerated for seven days. Furthermore, sodium metabisulfide (5 mg L⁻¹) was added into the medium in order to prevent the microbial contamination. In addition, the manure syrup was waited in 121°C in an autoclave for 15 min sterilizing. 24 h after the commencement of the experiment, 8.5 g L⁻¹ of sodium bicarbonate was also added. The experiment was conducted in 10 L of glass tanks in discontinuous mode for 10 days. Each of them was aerated by a central aeration system.

The nutrient media and quantities used in the experiment are shown in Table 1. The addition of urea and sodium bicarbonate was conducted at the time of feeding. The experiments were conducted in two different types of nutrition on 4 x 3 experimental designs, in 8 groups each, three times repeatedly.

The calculation of filament number and specific growth rate of S. platensis

Single drop method was used in the calculation of filament number (Semina, 1978). After each sample was counted at least 3 repeats, the filament number at 1 ml was calculated. In the experiment, the specific growth rate of Spirulina was calculated according to the formula below (Guillard, 1973):

\[ \mu = \frac{\ln N_t - \ln N_0}{t_1 - t_0} \]

\( \mu \): Specific growth rate, \( N_t \): Number of cells at the end of the experiment, \( N_0 \): Initial cell number, \( t \): Time (day).

\[ k = \mu / 0.6931 \]

Division, **k**, was evaluated according to \( k \) equation (Guillard, 1973; Mubeen et al., 2011).

Chemical analysis

Kjeldahl method (AOAC, 1984) was applied in the protein analysis and Blig and Dyer (1959) method was applied in lipid analysis.

Statistical analysis

The statistical analysis were made using SPSS 16.0 software package and the comparisons were carried out with one-way ANOVA-Duncan method.

RESULTS AND DISCUSSION

In the type I nutrition, the increase of cells in the type I group of the sixth day are detected respectively as follows: 326.67 filament ml\(^{-1}\); 336.33 filament ml\(^{-1}\); 357.67 filament ml\(^{-1}\); 317.67 filament ml\(^{-1}\); 260.33 filament ml\(^{-1}\) and are found to be different statistically in comparison to other groups (p<0.05). In the type I nutrition, average cell increase (289.70 filament ml\(^{-1}\)) was found to be in the highest level (Figure 1). In the experiment; in the type I nutrition, the ideal cell increase was detected in the type I group nutrition, the average increase of cell (296.50 ml\(^{-1}\)) was found to be the ideal (p<0.05) (Figure 1). In the type II nutrition, from the second day, the increase of cell in the type II group were defined respectively; 324.00 filament ml\(^{-1}\); 311.33 filament ml\(^{-1}\); 320.33 filament ml\(^{-1}\); 318.67 filament ml\(^{-1}\); 345.00 filament ml\(^{-1}\); 325.00 filament ml\(^{-1}\); 259.33 filament ml\(^{-1}\); 233.00 filament ml\(^{-1}\); 220.00 filament ml\(^{-1}\). However, in the type II group nutrition, the average increase of cell (296.50 ml\(^{-1}\) filament) was found to be the ideal (p<0.05) (Figure 1). In the type II nutrition, from the second day, the increase of cell in the type I group were defined respectively; 340.00 filament ml\(^{-1}\); 321.33 filament ml\(^{-1}\); 329.00 filament ml\(^{-1}\); 302.67 filament ml\(^{-1}\); 270.00 filament ml\(^{-1}\); 231.33 filament ml\(^{-1}\); 165.33 filament ml\(^{-1}\). From sixth day, any considerable difference was not found between type II group with type I group and other groups(p>0.05). But, significant differences were found between type II group with other groups after sixth day (p<0.05). The highest increase of cell took place in the type II nutrition due to the rates of urea and sodium bicarbonate which was halved compared to the type I nutrition. However, as opposed to the increase of cell, decrease in the rates of protein was observed. The reason for this is the nitrogen source and levels being one of the most important factors affecting the growth and biochemical contents in algae cultures. The growth is affected by concentrations as well as by nourishing elements that are used in the nutrition environments (Xu et al., 2001). It is concluded that the decrease in the protein ratios is the result of sodium bicarbonate pressuring the nitrogen levels in the environment, slowing down the protein metabolism and augmenting carbohydrate metabolism.

In the type I nutrition, the specific growth rates in the second, fourth, sixth, seventh and eighth days were recorded as being respectively; 0.07 division day\(^{-1}\); 0.01 division day\(^{-1}\); 0.21 division day\(^{-1}\); 0.03 division day\(^{-1}\); 0.06 division day\(^{-1}\). The most ideal specific growth rate in the type I group was found to be 0.21 division day\(^{-1}\) and k value as being 0.30 division day\(^{-1}\). The specific growth rate in the type II group, in the second day was found to be 0.06 division day\(^{-1}\) and the k value as 0.09 division
Figure 1. Daily increases in filament densities of *S. platensis* were cultivated in I and II type of nutrition with DCM.

The specific growth rate in the type III group, in the second day was found to be 0.36 division day\(^{-1}\) and the k value as 0.52 division day\(^{-1}\). The specific growth rate in the control group, in the eighth day was found to be 0.04 division day\(^{-1}\) and the k value as 0.06 division day\(^{-1}\) (Figures 2 and 3). In the type II nutrition, the specific growth rates in the second, fourth and the fifth day were recorded respectively; 0.04 division day\(^{-1}\); 0.03 division day\(^{-1}\); 0.05 division day\(^{-1}\). The specific growth rates in the second day were recorded to be 0.04 division day\(^{-1}\) and the k value as being 0.06 division day\(^{-1}\); in the fourth day was 0.03 division day\(^{-1}\) and the k value as being 0.04 division day\(^{-1}\); in the fifth day was 0.05 division day\(^{-1}\) and the k value as 0.07 division day\(^{-1}\). The specific growth rates in the second, fourth and the sixth day were recorded respectively; 0.05 division day\(^{-1}\); 0.03 division day\(^{-1}\); 0.08 division day\(^{-1}\).

The highest specific growth rate in the type II group was found to be 0.08 division day\(^{-1}\) and the k value is recorded as 0.12 division day\(^{-1}\). The specific growth rate in the type III group is recorded as 0.06 division day\(^{-1}\) and the k value as 0.09 division day\(^{-1}\). The specific growth rates in the control group in the third, fourth and the seventh day were recorded respectively; 0.08 division day\(^{-1}\); 0.12 division day\(^{-1}\); 0.02 division day\(^{-1}\). The specific growth rate in the control group in the fourth day is recorded to be 0.12 division day\(^{-1}\) and the k value as 0.17 division day\(^{-1}\) (Figures 2 and 3). Vonshak et al. (1982) reported that in the group where low cell increase had taken place, high specific growth was observed. Similarly, in our study in the groups where low cell increase had taken place, a maximum specific growth rate (µmax) was obtained. Vonshak et al. (1982) detected the µmax rates as 0.048 to 0.054 division day\(^{-1}\) and this is consistent with the specific growth rates (0.04 to 0.08 division day\(^{-1}\)) as we had obtained in our study.

There was no statistical discrepancies observed in the two different nutrition media in terms of lipid levels (p>0.05). Between I to II groups and III to IV groups of the type I nutrition media statistical discrepancies were found...
Figure 2. Daily increases in specific growth rates of *S. platensis* were cultivated in I and II type of nutrition with DCM.

(p<0.05). In the type II nutrition medium, there was a discrepancy found between I, II, III and IV groups (p<0.05). The lipid levels of *S. platensis* which was produced in the types I and II groups are found to be higher than that found in the types III and IV groups of both nutrition media (Figure 4). It can be concluded that the addition of sodium bicarbonate into the III and IV groups could be responsible. Vonshak et al. (1982) reported that this took place due to the partial CO₂ pressure of biomass values being high at high temperatures and the acceleration of photosynthesis. The results that the researchers reported support our findings. Danesi et al. (2002) reported that the lipid contents in the biomass of *S. platensis* are not under the influence of nitrogen source that was used. In our study, there was no discrepancy found in the lipid rates of the various concentrations of urea and sodium bicarbonate in both nutrition media. Our results are consistent with the results that Danesi et al. (2002) reported. Ungsethaphand (2009) reported that the highest protein content is obtained from the media in which urea and urea + sodium bicarbonate is added into the chicken manure. The increase in the protein content takes place due to the nitrogen levels increase in the environment (Ungsethaphand, 2009). In our study, the highest protein ratio is obtained from the groups in which urea and urea + sodium bicarbonate were added into the chicken manure. Our findings are consisted with the results that were obtained from the studies conducted by Ungsethaphand (2009).

In the study conducted by Koru and Cirik (2003), the protein ratio of *S. platensis* was reported to be 57.5% and the lipid ratio as 8%. In our study, the ratios of lipid and protein are found respectively, between 2.59 to 4.96, 35.51 to 44.98%. Based on the results that the researchers
Figure 3. Daily growth rates (division day\(^{-1}\)) of *S. platensis* were cultivated in I and II type of nutrition with DCM.

Figure 4. Lipid and protein ratio of *S. platensis* were cultivated in I and II type of nutrition with DCM.
reported, it was concluded that the low protein and lipid ratios that was obtained in our study is due to the differences in the nutrition media.

It was determined that usage of 1.0 mg/L urea+20 mg/L NaCO₃ added 200 mg/10 L of DCM (in type II nutrition) gave the best cellular increase and usage of 2.0 mg/L urea added 200 mg/10 L of DCM (in type I nutrition) gave the best cellular increase and the best protein ratio. In this case, we can say that suppressive effect of NaCO₃ decreased when the amount of urea and NaCO₃ had been halved.
