Accepted 6 May, 2011

Statistical experiment design and data analysis were used to establish the major factors in a chemically defined medium and to develop an ammonium control strategy to optimize the specific vitamin B_{12} production rate (Y_{p}) of *Pseudomonas denitrificans*. Through Plackett-Burman design, the major factors of glucose, ammonium sulfate and KCl were selected as the significant factors affecting vitamin B_{12} biosynthesis and these were further optimized by central composite design with response surface methodology. The maximum Y_{p} of 34.2 μg/gDCW/h was obtained in batch cultivation under the estimated optimal initial composition of glucose (93.6 g/l), (NH_{4})_{2}SO_{4} (7.93 g/l) and KCl (1.24 g/l). Ammonium control strategies in fed-batch fermentation showed that when ammonium concentration was maintained at 40 mmol/l, the maximum Y_{p} reached 36.0 ± 1.31 μg/gDCW/h, which was 57.2% higher than that of the control (22.9 ± 0.83 μg/gDCW/h). This ammonium control strategy successfully enhanced the industrial production, resulting in a stable high vitamin B_{12} production of 212.02 ± 3.03 mg/l and Y_{p} of 37.1 μg/gDCW/h.

Key words: Statistical designs, *Pseudomonas denitrificans*, chemically defined medium, ammonium controlling strategy, vitamin B_{12}.

INTRODUCTION

Two aspects are of critical importance in the successful industrial optimization of industrial vitamin B_{12} fermentation processes. Firstly, a full understanding is needed regarding the influence of nutritional composition on microbial fermentation. Secondly, the metabolism and physiological characteristics of the industrial microbial strains must be known in detail. A study on changes in intracellular metabolic flux distributions under different environments, combined with the real-time process parameters, would provide important information for fermentation optimization. Analysis of the correlation between primary metabolism and biosynthesis of the product of interest would also direct rational strain improvement through genetics and modification by molecular biology.

Vitamin B_{12} has a highly complicated molecular structure (Martens et al., 2002; Wang et al., 2010) that is biosynthesized from eight molecules of δ-aminolevulinic acid (δ-ALA). This δ-ALA precursor can be generated by either of two pathways (Figure 1): in the C4 pathway, δ-ALA is made from glycine and succinyl CoA by the action of ALA synthase. In the C5 pathway, the production of δ-ALA begins with glutamate (Lotfy, 2007). The results for a genetically engineered multi-enzyme synthesis of corrin showed that large amounts of the precursors, SAM, ATP and cofactor NADPH, generated via central carbon metabolism, are required for vitamin B_{12} production (Sano, 2009). Therefore, investigation of the relationship between central carbon metabolic pathways and secondary vitamin B_{12} biosynthesis is important. To better understand the metabolic flux distributions in vitamin B_{12} fermentation in *P. denitrificans*, ^{13}C-labeled metabolic flux analysis provides a powerful tool for effective quantification of all intracellular fluxes. This method has been widely utilized in a number of microorganisms including *Escherichia coli* (Dejaegher et al., 2007), *Bacillus clausii*...
Figure 1. Proposed overview of the pathway of vitamin B\textsubscript{12} biosynthesis by \textit{P. denitrificans} connected with the central metabolism. ACA, adenosyl cobyric acid; AcCoA, acetyl-CoA; APP, aminopropanol-2-phosphate; CIT, citrate; DMBI, dimethyl benzimidazole; F6P, fructose-6-phosphate; Gly, glycine; Glu, glutamate; G3P, glyceraldehyde-3-phosphate; G6P, glucose-6-phosphate; KDG, 2-Keto-3-deoxy-6-phosphogluconate; OAA, oxaloacetate; P5P, pentose-5-phosphate; PGA, 3-phosphate-glycerate; PYR, pyruvate; Ser, serine; SUC-CoA, succinyl-CoA; Thr, threonine; UPR, uroporphyrinogen III; α-KG, α-ketoglutarate; δ-ALA, δ-aminolevulinic acid.

(Choi et al., 1999), \textit{Penicillium chrysogenum} (Capp et al., 1996) \textit{Pseudomonas putida} (Berthouex and Brown 1994), hepatic cells (Demain et al., 1968) and \textit{Streptomyces tenebrarius} (Blank et al., 2008).

To carry out \textsuperscript{13}C-based metabolic flux analysis, a chemically defined medium is usually necessary in order to eliminate interference from unknown carbon sources on the isotopmer balance and metabolic flux ratio calculations. However, the productivity obtained under \textsuperscript{13}C-based chemically defined media is always dramatically lower than that obtained using the complex media commonly used in industrial production. As well, the physiological characteristics of the microorganisms can also dramatically differ when grown under these two diverse conditions. Therefore, an appropriate medium is necessary for the effective \textsuperscript{13}C metabolic network analysis in industrial microbial strains.

A clearly defined compositional medium could also provide an effective platform for investigating the effects of various factors on metabolism and productivity. In industrial vitamin B\textsubscript{12} fermentation, the by-products like beet molasses and corn steep liquor are extensively used as carbon and nitrogen sources. However, the uncertain component and different quality of materials
frequently results in large fluctuations of industrial fermentation. These have also been reported in fermentations of cephalosporin C (Li et al., 2008b), erythromycin (Warren et al., 2002) and avermectins. Therefore, determining the significant factors seriously affect the industrial productivities and developing an optimal controlling strategy would prove useful for improving these fermentation techniques.

This study presented experiments designed to screen and optimize a chemically defined medium for vitamin B₁₂ production by *P. denitrificans*, using Plackett-Burman design and central composite design. The effects of ammonium concentrations on vitamin B₁₂ fermentation, based on this medium, were also investigated in fed-batch fermentation. An optimal ammonium control strategy was also successfully applied to enhance industrial vitamin B₁₂ production.

**MATERIALS AND METHODS**

**Media for *P. denitrificans***

Pre-culture of *P. denitrificans* (donated by Huarong Pharmacy Corporation, Shijiazhuang, China) (Kanda, 1995) was performed in shake flasks (2000 ml) containing 250 ml medium composed of 0.5 g/l (NH₄)₂SO₄; 1.5 g/l (NH₄)₂HPO₄; 0.5 g/l MgSO₄·7H₂O; and 0.1 g/l ZnSO₄·7H₂O adjusted to pH 7.2 to 7.4 with 5 N NaOH. Separately sterilized glucose as the carbon source was added into the medium to a final concentration of 18 g/l just before inoculation. The composition of the initial medium for shake flask fermentation was as follows (g/l): glucose, 40; (NH₄)₂HPO₄, 7; KCl, 0.2; MgSO₄·7H₂O, 1.4; (NH₄)₂SO₄, 5; betaine, 12.0; 5,6-dimethylbenzimidazole (DMBI), 0.0065; trace element solution (TES) (100 ml). TES was composed of (g/l): MnSO₄·H₂O, 0.2; ZnSO₄·7H₂O, 0.2; CoCl₂·6H₂O, 0.025; FeSO₄·7H₂O, 0.03; and Na₂MoO₄, 0.02. The pH of the medium was adjusted to 7.2 to 7.4. The medium used in the research of Li et al. (2000) was adapted here in the industrial bioreactor fermentation (10,000 L), with corn steep liquor as the main nitrogen source.

**Shake flask culture**

Pre-culture was carried out in a 500 ml Erlenmeyer flask containing 100 ml of seed medium inoculated with cells from a fresh slant and cultured at 28°C on a rotary shaker at 260 rpm for 18 h. The seed culture was then transferred to a 500 ml Erlenmeyer flask containing 50 ml fermentation medium with 10% inoculum and incubated at 32°C on a rotary shaker at 260 rpm for 120 h.

**15 L bioreactor fed-batch culture**

Fed-batch fermentations were performed in a 15 L turbine-agitated bioreactor (Shanghai Guoqiang Inc., China) with a 10 L working volume. The inoculum was 10% (v/v) of the whole volume of the culture broth. The fermentation temperature and agitation speed were adjusted to 32°C and 400 rpm, respectively. The aeration rate was 0.8 vvm and the pH was controlled automatically at 7.0 to 7.2 with 3 M NaOH. The fed-batch processed combined pulse feeding of ammonium sulfate solution (400 g/l) to control the ammonium concentration. Each condition was tested twice and the data shown represent the mean values. Previous research found that dissolved oxygen concentration was sustained at a zero level constantly during fermentation because of the high oxygen consumption rate of *P. denitrificans* and an uptake rate controlling strategy was also applied in this research (Scott, 2003). When the total sugar in the broth dropped to 20 g/l, feeding of glucose solution (500 g/l) began and the residual glucose concentration was maintained at 1.5 to 2.0% throughout the entire fermentation process.

**10,000 L bioreactor fed-batch culture**

In a 10,000 L fermenter, the first seed culture was prepared in a 150 L seed fermenter containing 100 L sterile medium with inoculums from eight fresh slants. Cultivation was carried out at 28°C for 40 h with an aeration rate at 0.5 vvm and agitation speed at 180 rpm. Then the primary seed culture (70 to 80 L) was transferred into a 1,000 L secondary seed fermenter with 700 L of seed medium. It was cultivated at 28°C with stirrer speed at 130 rpm and aeration rate at 0.4 vvm for 30 h. Fermentation was performed in a 10,000 L fermenter equipped with three 3-bladed propeller impellers, a temperature probe, pH probe (Mettler Toledo) and dissolved oxygen probe (Mettler Toledo). The pH of the fermentation medium was adjusted to 7.0 and 7.2 before inoculation. The second seed (about 5% of the final working volume) was transferred into 10,000 L fermenter with 7,500 L working volume. The fermentation process was carried out at 32°C for 166 h. The glucose feeding strategies were similar to that mentioned earlier in the 15 L bioreactor.

**Determination of dry cell weight (DCW) and vitamin B₁₂**

Samples were centrifuged at 8000 g for 10 min and washed twice with distilled water; the cell precipitate was dried to a constant weight at 105°C. The vitamin B₁₂ concentration was determined by HPLC. Broth samples (25 ml), to which 2.5 ml of 8% NaNO₃ and 2.5 ml of acetic acid were added, were boiled for 30 min, then the upper aqueous phase was measured using a HPLC system equipped with a C₁₈ column, (4.6 mm, 25 cm and 5 μm) with an UV detector (254 nm). 85% of 0.25 M sodium acetate anhydrous (pH was adjusted to 3.6 with acetic acid) and 15% of methanol in water was used as the mobile phase with a flow of 1.0 ml/min at 40°C (Kamarthapu et al., 2008).

**Determination of ammonium and δ-aminolevulinic acid (δ-ALA) concentrations**

The concentrations of ammonium-nitrogen (NH₄⁺-N) in broths were quantified by the method described by Kanda, which uses O-phenylphenol as a substitute for liquid phenol (Hofmann et al., 2008). δ-ALA concentration in the fermentation broth was determined according to the method reported by Choi et al. (1999).

**Experimental design and data analysis**

For selection of significant factors for vitamin B₁₂ production, eight independent variables, including glucose, KCl, Na₂HPO₄, MgSO₄, betaine, (NH₄)₂HPO₄, (NH₄)₂SO₄ and TES, were tested and identified via the Plackett-Burman design (Christensen and Nielsen, 2000). All trials were carried out in triplicate and the average vitamin B₁₂ yields were treated as responses. The main effect of each variable was simply calculated as the difference...
between the average of measurements made at the high setting (+1) and low setting (-1) for that factor. The experimental design is shown in Table 1. The Plackett-Burman experimental design is based on the first order model (Equation 1):

\[ Y = \beta_0 + \sum \beta_i X_i \]  

(1)

Where, \( Y \) is the response (vitamin \( B_{12} \) yield), \( \beta_0 \) is the models intercept, \( \beta_i \) is the linear coefficient and \( X_i \) is the level of the independent variable.

This model does not describe the interactions among factors; it is used to screen and evaluate the important factors that influence the response. The significance of each variable was determined via Student’s \( t \)-test using SAS software.

The next step in the formulation of the medium was to determine the optimum levels of significant variables for vitamin \( B_{12} \) production. For this purpose, the response surface methodology (RSM) was used for the augmentation of total vitamin \( B_{12} \) production (Li et al., 2008a). The significant variables utilized were as follows: glucose, KCl and \((NH_4)_2SO_4\), each of which was assessed at five coded levels (-1.68, -1, 0, +1 and +1.68) and a total of 20 experiments were carried out, as shown in Table 3. All variables were taken at a central coded value, which was designated as zero. The minimum and maximum ranges of the variables were used and the full experimental plan with regard to their values in actual and coded form is provided in Table 3. The statistical software package Design-Expert-7.0 was used to generate the model to predict the effect of combined variables on vitamin \( B_{12} \) production. For a three-variable system, the responses can be predicted by the following second-order regression equation:

\[ Y = \beta_0 + \beta_1 X_1 + \beta_2 X_2 + \beta_3 X_3 + \beta_11 X_1^2 + \beta_22 X_2^2 + \beta_33 X_3^2 + \beta_12 X_1 X_2 + \beta_13 X_1 X_3 + \beta_23 X_2 X_3 \]  

(2)

Where, \( Y \) is the dependent variable (vitamin \( B_{12} \) yield or specific vitamin \( B_{12} \) production rate); \( X_1, X_2 \) and \( X_3 \) are the independent variables as mentioned earlier; \( \beta_0 \) is the regression coefficient at center point; \( \beta_1, \beta_2 \) and \( \beta_3 \) are linear coefficients; \( \beta_{12}, \beta_{13} \) and \( \beta_{23} \) are second order interaction coefficients; \( \beta_{11}, \beta_{22} \) and \( \beta_{33} \) are quadratic coefficients. The values of the coefficients, the optimum levels and \( R^2 \) were determined as mentioned earlier.

### RESULTS AND DISCUSSION

Evaluation of significant variables by Plackett-Burman Design.

The design matrix selected for the screening of significant variables for vitamin \( B_{12} \) production and the corresponding responses are shown in Table 1. The adequacy of the model was calculated and the variables showing statistically significant effects were screened via Student’s \( t \)-test for ANOVA with SAS statistical software (Table 2). Factors showing \( p \)-values of less than 0.05 were considered to have significant effects on the response and were therefore, selected for further optimization studies. Glucose, with a probability value of 0.0018 was determined to be the most significant factor, followed by \((NH_4)_2SO_4\) (0.0115) and KCl (0.0298). Glucose had a positive effect on the vitamin \( B_{12} \) production. Vitamin \( B_{12} \) is a highly complicated molecule as it contains a tetrapyrrole-derived macrocycle (Martens et al., 2002; Wang et al., 2010) and somewhere around 30 genes are necessary for its complete \emph{de novo} biosynthesis (Wang et al., 2010). In these processes, large amounts of energy and cofactors were required for maintenance and vitamin \( B_{12} \) production in the oxygen-dependent fermentation by \emph{P. denitrificans} (Sano, 2009). Therefore, a high glucose concentration is necessary for greater vitamin \( B_{12} \) production. Nitrogen as \((NH_4)_2SO_4\) also plays an important role in cell

$R^2$ (coefficient of determination) = 0.99; X1, glucose (g/l); X2, KCl (g/l); X3, (NH$_4$)$_2$SO$_4$ (g/l).

growth and product fermentation and higher vitamin B$_{12}$ production was achieved as N source concentrations were increased. Statistical analysis also showed that KCl had a significant effect on vitamin B$_{12}$ production. As is well known, K$^+$ has a significant function in the regulation of intracellular osmosis. The K$^+$ concentrations in the cytoplasm of growing cells increases greatly with increases in osmolarity of the defined growth medium to allow expulsion of redundant putrescine (Borodina et al., 2005).

Vitamin B$_{12}$ biosynthesis requires eight methylation reactions, with S-adenosylmethionine (SAM) serving as the methylating agent. Kamarthapu et al. (2008) proposed that, SAM synthetase was stimulated by the monovalent cation K$^+$ at 100 mM and the further research demonstrated the presence of conserved amino acids at positions D286 for the K$^+$ binding site, confirming the need for K$^+$ for SAM synthetase activity. Betaine is an important methyl-group donor for vitamin B$_{12}$ biosynthesis in P. denitrificans (Lofty et al., 2007). In this study, betaine concentrations from 2.5 to 5.5 g/l had little effect on vitamin B$_{12}$ production, so betaine concentration was selected at 2.5 g/l. All other non-significant variables were neglected and the optimum
levels of the three variables, glucose, (NH₄)₂SO₄ and KCl were further determined by RSM design.

Optimization of fermentation conditions by central composite design

The experimental design, the levels of vitamin B₁₂ production and the specific productivity obtained from different concentrations of additives are summarized in Table 3.

The experimental levels of vitamin B₁₂ production and the specific productivity were used to generate the second-order regression models. A second order polynomial function was fitted to the experimental results of vitamin B₁₂ production and the specific productivity with statistical software. The response of vitamin B₁₂ production (Y) and the specific vitamin B₁₂ production rate (Y₀) can be expressed in terms of the following regression equations (3, 4), respectively:

\[
y = 63.99 + 1.65X₁ - 0.27X₂ - 1.23X₃ - 7.31X₁² - 4.13X₂² - 4.21X₃² - 0.5X₁X₂ + 0.43X₁X₃ + 2.03X₂X₃
\]

\[
y₀ = 30.5 - 0.33X₁ + 2.36X₂ + 2.62X₃ - 0.41X₁² - 1.16X₂² - 1.94X₃² + 0.04X₁X₂ + 1.31X₁X₃ - 0.51X₂X₃
\]

The quality of fit of the second-order regression equations was checked using the coefficient of determination \( R² \) (multiple correlation coefficient) and was calculated to be 0.9902 and 0.995 with vitamin B₁₂ production and the \( Y₀ \) as the response, respectively, indicating that 99.02 and 99.5% of the variability in the response could be explained by the model. The ANOVA table is presented in Table 4. The model F-values of 112.11 and 21.19 showed the models were significant and the adequacy of second-order regression models. According to the linear coefficients of second-order equations, statistical analysis demonstrated that glucose and (NH₄)₂SO₄ had significant effects on vitamin B₁₂ production, while KCl and (NH₄)₂SO₄ both had considerable effects on the \( Y₀ \) within the tested ranges, at the probability level of 95%.

For predicting these optimal points mathematically, second-order regression models were used to develop response surface curves relating vitamin B₁₂ productivity to various levels of additives. Figures 2 and 3 showed the response surface plot for vitamin B₁₂ production and \( Y₀ \) as a function of KCl and (NH₄)₂SO₄ and glucose, respectively. By moving along the X and Y axes, it can be demonstrated that increasing the levels of KCl and (NH₄)₂SO₄ had a conspicuous effect on vitamin B₁₂ production (Figure 2). As a result, the stationary ridge shape was observed on the surface plot of the two fermentation parameters and the maximum response inside the design boundary. Based on the medium optimization evaluated from the model of Equation 3, the predicted largest vitamin B₁₂ yield was 67.2 mg/l when the glucose, (NH₄)₂SO₄ and KCl concentration were 72.2, 7.85 and 0.98 g/l, respectively. Figure 3 showed the interaction of glucose and (NH₄)₂SO₄ had a significant effect on \( Y₀ \), the plot exhibited that higher concentrations of glucose and (NH₄)₂SO₄ were favorable for the \( Y₀ \). The maximum predicted \( Y₀ \) of 33.3 μg/gDCW/h was attained when the glucose, (NH₄)₂SO₄ and KCl concentration were 93.6, 7.93 and 1.24 g/l, respectively. The results showed that higher initial concentrations of glucose and KCl were important for accelerating the vitamin B₁₂ biosynthesis rate of P. denitrificans, while lower glucose concentration was favorable for higher vitamin B₁₂ production.

The verification experiments carried out at two optimal conditions showed the observed experimental vitamin B₁₂ production and the \( Y₀ \) was 65.8 ± 1.5 mg/l.

and 34.2 ± 1.0 μg/gDCW/h, respectively, which were approximately 103.3 and 87.5% higher than that of the control (32.4 ± 1.3 mg/l and 18.2 ± 0.7 μg/gDCW/h with basal medium before applying P-B optimization). The great similarity between the predicted and observed results demonstrated the accuracy and applicability of
Ammonium controlling strategies in fed-batch fermentation (15 L) with chemically defined media

Vitamin B<sub>12</sub>, a secondary metabolite of <i>P. denitrificans</i>, was mainly synthesized during the stationary growth period, and the fed-batch cultivation was applied in vitamin B<sub>12</sub> fermentation of <i>P. denitrificans</i>. Except for the initial nutrients, the components of the medium in the stationary state of cell growth also exerted significant effects on vitamin B<sub>12</sub> biosynthesis. The earlier mentioned results had proved that (NH<sub>4</sub>)<sub>2</sub>SO<sub>4</sub> was the significant factor for both vitamin B<sub>12</sub> production and the specific B<sub>12</sub> production rate (μg/gDCW/h). Ammonium controlling strategies: control, with the basal fermentation medium and not ammonium controlled; Run-a, Run-b and Run-c: the ammonium concentration were controlled at 22 ± 1.8, 40 ± 2.0 and 65 ± 2.5 mmol/l by feeding ammonium sulfate solution in vitamin B<sub>12</sub> fermentation with optimal medium, respectively.

The central composite design as an extremely powerful method for optimizing the vitamin B<sub>12</sub> medium (Li et al., 2000).

the earlier mentioned results had proved that (NH<sub>4</sub>)<sub>2</sub>SO<sub>4</sub> was the significant factor for both vitamin B<sub>12</sub> production and the specific B<sub>12</sub> production rate (μg/gDCW/h). used as the control.

As shown in Table 5, the period of batch phase in optimal chemically defined medium was only 37.5 ± 0.8 h, less than that of the control (48 ± 1.5 h) and the cell growth rate was 41.7 to 61.2% higher than that of the control. Cell growth rate was enhanced by the increased ammonium concentration. A pronounced enhancement of vitamin B\textsubscript{12} synthesis was achieved under an ammonium concentration of 40 ± 2.0 mmol/l and the final vitamin B\textsubscript{12} production was 165 ± 2.2 mg/l, which was 84.4% greater than that of the control. The specific vitamin B\textsubscript{12} production rate (Y\textsubscript{p}) also increased when the ammonium concentration increased to 40 ± 2.0 mmol/l. The maximum Y\textsubscript{p} reached 36.0 ± 1.31 μg/gDCW/h; 57.2% higher than that of the control (22.9 ± 0.83 μg/gDCW/h) in fed-batch fermentation (Table 5). However, when ammonium concentration increased to 65 ± 2.5 mmol/l, vitamin B\textsubscript{12} biosynthesis was dramatically inhibited, the vitamin B\textsubscript{12} production decreased to 93.5 ± 2.2 mg/l and the Y\textsubscript{p} dropped to 19.1 ± 2.07 μg/gDCW/h. Determination of the intermediates showed that higher specific secretion rates of glycine, glutamate and succinate were obtained when the ammonium concentration was increased to 40 ± 2.0 mmol/l. These intermediates were the critical precursors of δ-ALA biosynthesis and thus, promoted vitamin B\textsubscript{12} production. Glutamate joint the transaminase for many amino acids biosynthesis and ammonium was necessary for the biosynthesis of glutamate from α-ketoglutarate by reductive ammonia fixation via glutamate dehydrogenase (Muller et al., 1989). Therefore, maintaining the appropriate ammonium concentration at 40 ± 2.0 mmol/l was favorable for higher glutamate production. The other amino acids such as aspartate, serine, alanine and organic acids α-ketoglutarate and acetate showed little difference under all the four conditions. However, under the highest ammonium concentration of 65 ± 2.5 mmol/l, the specific secretion rate of glycine, glutamate and succinate were significantly decreased. This might be caused by the significant inhibition of high ammonium concentration on the activity of pyruvate dehydrogenase and then led to the highest specific puruvate accumulation rate of 121.1 ± 13.8 μg/gDCW/h, which were 9 folds higher than that of the other conditions. Overall, the control of the ammonium concentration at 40 mmol/l led to higher accumulation of relevant intermediates and therefore, greater vitamin B\textsubscript{12} biosynthesis by \textit{P. denitrificans}.

Scale-up of the optimal ammonium control strategy in a 10 m\textsuperscript{3} fermenter

The results from the fed-batch fermentation with a chemically defined medium demonstrated that the nitrate source levels had significant effects on vitamin B\textsubscript{12} fermentation. In vitamin B\textsubscript{12} fermentation, the by-products like beet molasses and corn steep liquor are extensively used as nitrogen sources due to their low
cost. The vitamin B\textsubscript{12} productivities in large-scale industrial fermentation were always tremendously influenced by the uncertainty of the components and changing quality of raw materials, especially the large differences in the nitrogen content of the raw materials. Therefore, in order to eliminate negative effects of nitrogen content fluctuation in the medium on vitamin B\textsubscript{12} production, the optimal ammonium controlling strategy was implemented on the industrial fermentation in a 10 m\textsuperscript{3} fermenter with complex medium. Figure 5 shows the kinetics of ammonium concentration, biomass growth, vitamin B\textsubscript{12} production and δ-ALA in large-scale fermentations with and without ammonium controlling strategy. As cell growth increased, the residual ammonium concentrations decreased sharply to 15.0 ± 3.0 mmol/l at 37 ± 2.8 h at the two kinds of cultivation and then ammonium concentrations were maintained at 35 to 43 mmol/l by pulse feeding of ammonium sulfate solution, compared with that of the control(Figure 5a). The cell growth, δ-ALA concentration and vitamin B\textsubscript{12} production had no different before the ammonium concentration was controlled. Although, the cell growth with the ammonium controlled cultivation had little higher than that of the control (Figure 5b), a remarkable enhancement of vitamin B\textsubscript{12} biosynthesis was achieved under ammonium controlled cultivation (Figure 5c). A stably vitamin B\textsubscript{12} production reached 212.0 ± 3.0 μg/gDCW/h under ammonium controlling strategy, which was 14.6% higher than that of without ammonium control (31.6 μg/gDCW/h). Analysis of the δ-ALA concentrations showed that maintaining ammonium concentration at 35 to 43 mmol/l would greatly accelerate δ-ALA biosynthesis and the high flux of δ-ALA generation thus improved the vitamin B\textsubscript{12} production (Figure 5d). This ammonium control strategy was successfully applied to industrial production in a complex medium and a stable and higher vitamin B\textsubscript{12} production was achieved.

Previous research shown that glutamate and methionine are necessary for growth of \textit{P. denitrificans} in a chemically defined medium (Christiansen et al., 2002), while our results demonstrated that the industrial strain of \textit{P. denitrificans} can grow well with glucose as the sole carbon source. The specific vitamin B\textsubscript{12} production rate reached 36.0 ± 1.31 μg/gDCW/h under the optimal chemically defined medium in fed-batch fermentation, which was similar to that with a complex medium (37.1 μg/gDCW/h) in large-scale industrial production (Li et al., 2000). The physiological characteristics of \textit{P. denitrificans} in industrial vitamin B\textsubscript{12} production can be well implemented in this chemically defined medium. Therefore, the obtained optimal chemically defined medium and ammonium controlling strategy could be used for further 13C-metabolic flux analysis of \textit{P. denitrificans}, so as to reveal the metabolic network distributions and implement a rational optimization on industrial vitamin B\textsubscript{12} fermentation. Furthermore, a stable high productivity and more economic industrial vitamin B\textsubscript{12} production were successfully achieved.

**Conclusion**

In this research, glucose, ammonium sulfate and KCl were selected as the major factors affecting vitamin B\textsubscript{12} productivity of \textit{P. denitrificans} from eight varieties through P-B design and the optimal concentration and the interaction between these factors were estimated with RSM design and a second-order polynomial model. Further experiments showed that maintaining the ammonium concentration at 35 to 43 mmol/l was necessary for enhanced vitamin B\textsubscript{12} biosynthesis. One advantage of optimizing a chemically defined medium and establishing a control strategy was that a higher specific vitamin B\textsubscript{12} production rate was achieved, which was similar to that of an industrial complex-medium condition. In addition, the ability to use glucose and inorganic ammonium as the sole carbon and nitrogen sources should allow further metabolic flux analysis on vitamin B\textsubscript{12} fermentation of \textit{P. denitrificans} by 13C labeling experiments, as the influence of unlabeled carbon sources on labeling abundance is eliminated. The ammonium controlling strategy was able to prevent the fluctuation in total-N concentrations of the raw materials in industrial production, allowing a stable 20.5% augmentation of B\textsubscript{12} production.
