Abstract:

**Background:** *Pseudomonas aeruginosa* has been highly associated with carbapenem resistance in which carbapenemases has been suggested to be a major contributory factor. Hence the objective of this study was to phenotypically detect KPC-type carbapenemase, metallo-β-lactamase and OXA-48 carbapenemase production in clinical isolates of *P. aeruginosa* in Lagos University Teaching Hospital (LUTH), Nigeria

**Methodology:** One hundred and seventy-one *P. aeruginosa* isolates consecutively recovered from clinical specimens of patients with infections at the Medical Microbiology and Parasitology laboratory of the hospital were identified using Microbact™ 24E kit. Preliminary screening for carbapenem resistance was determined by the disc diffusion method on Mueller-Hinton agar using single discs of meropenem and imipenem. Phenotypic detection of carbapenemase production among carbapenem-resistant isolates was performed by the combination disc test of meropenem-phenylboronic acid (MRPBO) and meropenem-dipicolinic acid (MRPDP) as recommended by EUCAST 2013 guideline.

**Results:** Out of the 171 *P. aeruginosa* isolates, 35 (20.5%) were carbapenem non-susceptible (resistant) while carbapenemase production was detected in 27 (77.1%) of these carbapenem resistant isolates, and no enzyme was detected in 8 (22.9%). Of the 27 carbapenemase producing isolates, 22 (81.5%) produced MBL, 1 (3.7%) produced KPC, while 4 (14.8%) produced both KPC and MBL enzymes.

**Conclusion:** This study revealed that carbapenem resistance among *P. aeruginosa* clinical isolates in our institution is gradually increasing. The mechanism for this rise is associated with carbapenemases, with MBL being the major carbapenemase involved. There is the need to ensure strict compliance with the LUTH infection control guidelines in order to check the rising incidence of infection caused by carbapenem resistant *P. aeruginosa*.

Abstrait:

**Contexte:** *Pseudomonas aeruginosa* a été fortement associé à la résistance aux carbapénèmes dans laquelle les carbapénèmes ont été suggérées comme étant un facteur contributif majeur. Par conséquent, l’objectif de cette étude était de détecter phénoménalement la production de carbapénémase de type KPC, de métallo-β-lactamase et de carbapénémase OXA-48 dans des isolats cliniques de *P. aeruginosa* au Lagos University Teaching Hospital (LUTH), Nigeria.
Méthodologie: Cent soixante et onze isolats de P. aeruginosa récupérés consécutivement à partir d’échantillons cliniques de patients infectés au laboratoire de microbiologie médicale et de parasitologie de l’hôpital ont été identifiés à l’aide du kit MicrobactTM 24E. Le dépistage préliminaire de la résistance aux carbapénèmes a été déterminé par la méthode de diffusion sur disque sur gélose Mueller-Hinton en utilisant des disques uniques de méropénème et d’imipénème. La détection phénotypique de la production de carbapénèmes parmi les isolats résistants aux carbapénèmes a été réalisée par le test de disque combiné d’acide méropénème-phénylboronique (MRPBO) et d’acide méropénème-dipicolinique (MRDPD) tel que recommandé par la directive EUCAST 2013.

Résultats: Sur les 171 isolats de P. aeruginosa, 35 (20,5%) étaient des carbapénèmes non sensibles (résistants) tandis que la production de carbapénèmes a été détectée dans 27 (77,1%) de ces isolats résistants aux carbapénèmes, et aucune enzyme n’a été détectée dans 8 (22,9%). Sur les 27 isolats producteurs de carbapénèmes, 22 (81,5%) produisaient des MBL, 1 (3,7%) produisaient des KPC, tandis que 4 (14,8%) produisaient à la fois des enzymes KPC et MBL.

Conclusion: Cette étude a révélé que la résistance aux carbapénèmes parmi les isolats cliniques de P. aeruginosa dans notre institution augmente progressivement. Le mécanisme de cette augmentation est associé aux carbapénèmes, la MBL étant la principale carbapénémase impliquée. Il est nécessaire de garantir le strict respect des directives de contrôle des infections LUTH afin de contrôler l’incidence croissante des infections causées par P. aeruginosa résistant aux carbapénèmes.

Mots-clés: carbapénémase; CPK; MBL; OXA-48; Pseudomonas aeruginosa; isolats cliniques

Introduction:

Pseudomonas aeruginosa est un membre de la famille des Gamma Proteobacteria, a Gram-negative aerobic bacillus belonging to the family Pseudomonadaceae (1). Pseudomonas aeruginosa is associated with varying degree of infections ranging from mild to severe infections. These include otitis externa, urinary tract infection, lower respiratory tract infections, folliculits, keratitis, infection of corneal ulcers, endophthalmitis and opportunistic blood stream infection in immunocompromised patients. It is also an important cause of nosocomial infections such as ventilator-associated pneumonia and wound infections in burn patients, and causes damage to the lung tissue with decreased pulmonary function in patients with cystic fibrosis (2,3). Pseudomonas aeruginosa is rarely a part of the microbial flora of healthy individuals, but may colonize the gastrointestinal tract of hospitalized patients, particularly neutropenic patients who have received previous antibiotic therapy (3). Pseudomonas aeruginosa is notoriously resistant to a number of antibiotics and only a handful of antibiotics are effective for treating infections caused by P. aeruginosa.

Carbapenems are class of β-lactam antibiotics with a broad spectrum antibacterial activity. They are used in the treatment of severe infections caused by bacteria producing the extended-spectrum β-lactamases (ESBLs) or multi-drug resistant Pseudomonas spp overexpressing chromosomal AmpC β-lactamases (4). Carbapenems approved for clinical use includes imipenem, meropenem, ertapenem and doripenem (5). The widespread occurrence of community-acquired bacterial isolates producing ESBLs capable of hydrolyzing almost all β-lactam antibiotics except the carbapenems (6), led to increased use of the carbapenems, which became very crucial for treating life-threatening infections that are often associated with modern medical techniques and practice such as transplantation, intensive care unit hospitalization and highly technical surgery (7). The subsequent emergence of carbapenem resistance has been largely associated with carbapenemase production. However, the actual prevalence of carbapenemase-producing bacterial strains remains unknown because many countries worldwide do not report rates of antibiotic susceptibility (8).

Carbapenemases are carbapenem-hydrolyzing β-lactamases that are able to hydrolyze almost all β-lactams. Most are resilient against inhibition by commercially viable β-lactamase inhibitors (9). These enzymes are mostly of the Klebsiella pneumoniae carbapenemase (KPC), Verona integron-encoded metallo – β-lactamase (VIM), imipenemase (IMP), New Delhi metallo – β-lactamase (NDM) and oxacillinase-48 (OXA-48) types (10), which are enzymes in Ambler classes A, B, and D (9,11,12). The Ambler class A carbapenemases include the KPC (9,13,14), Serratia marcescens enzyme family (SME), imipenem-hydrolyzing β-lactamase (IMI), "Not metallo-enzymes carbapenemase" (NMC) (9,11) and Guiana extended spectrum (GES) beta-lactamases (15). Although the KPC and GES β-lactamases are predominately found in Enterobacteriaceae, there have been reports of these enzymes in P. aeruginosa (16-19). The Ambler class B metallo-β-lactamases (MBLs) include IMP, VIM-1, VIM-2, (20,21), NDM-1, GIM (22), and Seoul imipenemase (SIM) (23). However, VIM and IMP have been reported in P. aeruginosa (20). The Ambler class D serine-carbapenemases include oxacillin-hydrolyzing (OXA) β-lactamases in which P. aeruginosa is one of the organisms where it has been mainly implicated (11,24).

There are various strategies that have been proposed for detection of carbapenemases and the genes encoding them. A series of non-molecular tests have also been proposed for the detection of carbapenemase
Carbapenemase producing Pseudomonas aeruginosa clinical isolates

activity (7,25) such as the inhibitor-based method which depends on demonstrating synergy between an indicator carbapenem and various in-vitro β-lactamase inhibitors. MBL inhibitors include ethylenediamine tetraacetic acid (EDTA) and dipicolinic acid (DPA), while inhibitors of KPC and other class A carbapenemases are boronic acids, usually 3-aminophenylboronic acid (APBA) or phenylboronic acid (PBA), although the mechanism of inhibition is not known (26-32). There is no known specific inhibitor for OXA-48-like carbapenemases but the disc diffusion assay using temocillin besides PBA and DPA, is usually utilized since OXA-48 confers high-level temocillin resistance. The objective of this study is to determine the prevalence of phenotypic production of KPC, MBL and OXA-48 carbapenemases production in clinical isolates of P. aeruginosa in Lagos University Teaching Hospital, Nigeria

Materials and method:

Study setting

The study setting is Lagos University Teaching Hospital (LUTH), a 764-bed tertiary care hospital in Lagos, southwest region of Nigeria, which service covers the entire Lagos State and neighboring Ogun State.

Study design, protocol and ethical approval

This is a laboratory-based study of 171 P. aeruginosa isolates recovered by standard microbiological methods consecutively from clinical specimens of patients with infections, submitted to the Department of Medical Microbiology and Parasitology of the hospital between November 2014 and October 2015 (33). The isolates were identified to species level using the commercial MicrobactTM 24E (Oxoid, UK) kit according to the manufacturer’s instructions. The protocol for the study was approved by the Ethics Review committee of LUTH. Waiver of consent was approved and data were anonymized prior to analysis.

Screening and phenotypic detection of carbapenemase production

Screening for carbapenem resistance was determined by disc diffusion method on Mueller-Hinton agar using commercially available single discs of meropenem and imipenem (Oxoid, England, UK) (34). All isolates with zone diameter of inhibition less than the cut-off values for imipenem (<23mm) and/or meropenem (<25mm) (carbapenem resistant) were tested for phenotypic production of carbapenemases using the EUCAST 2013 guidelines (35). Phenotypic detection of carbapenemase production was performed by the combination disc test using commercially available tablets (Rosco Diagnostica Neo-Sensi-tabs, Rosco, Taastrup, Denmark) (36-37). The KPC/MBL in P. aeruginosa Confirm Kit version 2 (98025) was used for testing according to the manufacturer’s instructions.

The test was carried out on Mueller Hinton agar using the modified Kirby-Bauer method and EUCAST disk diffusion method 2013 version 3.0 (35). Few morphologically similar colonies of overnight pure culture isolates were inoculated into sterile normal saline and visible turbidity was adjusted to match the turbidity of 0.5 McFarland standards. The inoculum suspension was streaked onto Mueller-Hinton agar plate using a sterile swab stick. Tablets containing Meropenem 10µg (MRP10), Meropenem 10µg + Phenylboronic acid (MRPBO) and Meropenem 10µg + Dipicolinic acid (MRPDP) were applied and incubation was done at 35±1°C for 16-20 hours. The zone diameter of inhibition of each isolate to the tablets was measured using a calibrated ruler, and result interpreted using the EUCAST guideline.

When the zones of inhibition of MRP10, MRPBO and MRPDP were within 2mm of each other, the isolate was reported as not producing KPC and MBL. When the MRPBO showed a zone difference of ≥ 4mm from MRP10, the isolate was reported as demonstrating KPC activity. When MRPDP showed a zone difference of ≥5mm from MRP10, the isolate was reported as demonstrating MBL-β-lactamase activity. Only ceftazidime resistant isolates were tested, as false positive MBL may be obtained with ceftazidime sensitive isolates.

Results:

A total of 171 P. aeruginosa were tested for carbapenem resistance and subsequently tested for carbapenemase production. The isolates were recovered from patients with sepsis (n=3), ocular infections (n=5), otolaryngeal infections (n=22), chest infections (n=7), intra-abdominal infections (n=2), reproductive system infections (n=3), bone/joint infections (n=5), urinary tract infections (n=39), surgical site infections (n=16) and wound infections (n=69) (Table 1).

A total of 35 (20.5%) isolates were carbapenem non-susceptible (resistant) while carbapenemase production was detected in 27 (77.1%), and no enzyme was detected in 8 (22.9%) of the carbapenem resistant isolates. Of the 27 carbapenemase producing isolates, 22 (81.5%) produced MBL, 1 (3.7%) produced KPC, and 4 (14.8%) produced both KPC and MBL enzymes (Table 2).

Discussion:

In this study, the prevalence of carbapenem resistance among clinical isolates of P. aeruginosa in our institution was 20.5%. This
Carbapenemase producing Pseudomonas aeruginosa clinical isolates

is similar to the findings in Turkey and India where the prevalence of carbapenem resistant \( P. \) aeruginosa was 20% (38) and 18.2% (39) respectively. This rate is quite high for a drug which is usually reserved for last resort use. Previous studies carried out in our institution reported prevalence rates of carbapenem resistance among \( Pseudomonas \) isolates to be 4.1% in 2007 (40) and 5.9% in 2013 (33). Comparing the results of the two studies to this present one indicates that the prevalence of carbapenem resistance among \( P. \) aeruginosa isolates in our institution is increasing.

Carbapenemase production is the most predominant mechanism that confers clinically significant resistance to Gram-negative bacteria (GNB) (41-45), which is why most carbapenem-resistant \( P. \) aeruginosa isolates in our study (77.1%) produced carbapenemases. This high rate of carbapenemase production was also reported by Ogbolu et al., (46) with a rate of 59.7% and by Mohammed et al., (47) with a rate of 82.1% in other institutions in Nigeria. Also, a study conducted in India (39) using two different types of phenotypic testing methods reported a high rate of carbapenemase production of 93.1% (combined disk synergy test) and 87.2% (double-disk synergy test). It should be noted that 22.9% of the carbapenem resistant \( P. \) aeruginosa isolates in this study did not produce carbapenemase, which suggests that other resistance mechanisms such as over-production of AmpC cephalosporinase, drug efflux, and deficient production or loss of porins might be responsible for the carbapenem resistance in these isolates (48).

The most common carbapenemases produced by \( P. \) aeruginosa in this study were MBLs (81.5%) and KPC (3.7%), which is similar to the findings of Mushi et al., (49) in Tanzania, whereas KPC was reported to be more common than MBL by Vanegas et al., (50) in Colombia.

KPC = Klebsiella pneumoniae carbapenemase; MBL = metallo-\( \beta \)-lactamase
The KPC/MBL confirmation kit used in this study could not detect OXA-48 enzyme. A more recent phenotypic detection method such as the carbapenem inactivation method (CIM) which detects KPC, MBL and OXA-48 enzymes, may have detected the OXA-48 enzymes if used in this study. However, this method was not available to us at the time of this study. Similarly, molecular methods which are reported to be more sensitive and specific in detecting KPC, MBL and OXA-48 genes, were not available for this study.

Conclusion:

In conclusion, our findings revealed that carbapenem resistance among *P. aeruginosa* clinical isolates in our institution, is gradually on the rise, with carbapenemases being the major contributory mechanism for this, which is line with previous studies in this institution. Also, it is noteworthy to emphasize that *P. aeruginosa* can produce more than one class of carbapenemases as reported in our study, which raises some concern. Our findings also have serious implication for antimicrobial therapy of *P. aeruginosa* infections and infection control measures in our environment, in view of the fact that new antibiotics are not forthcoming. Hence, the need to preserve the antibiotics we have now by embracing antimicrobial stewardship.
