Received for publication on 8 September 2008. Accepted in revised form 13 October 2008

Key words: Inflammatory bowel disease, Ulcerative colitis, Crohn's disease, Indeterminate colitis, Juvenile onset inflammatory bowel disease.

ABSTRACT

Background & Aims: Inflammatory bowel disease is thought to be rare in Libya. The aim is to determine the prevalence of juvenile onset inflammatory bowel disease in Libya. Setting: Al-Fateh children's hospital, Benghazi, Libya. Methods: This is a retrospective study of all cases diagnosed over 10 years (1997-2006) with either ulcerative colitis, Crohn's disease or indeterminate colitis. Inclusion criteria were age <15 years at time of presentation who were resident in the eastern part of the country and who diagnosed with inflammatory bowel disease. Clinical features were outlined using a proforma. Results: Sixteen cases were diagnosed with inflammatory bowel disease, of whom 11 were males (M:F ratio of 1.5:1). The prevalence and incidence rates in the year 2006 were 3.6 and 0.9 per 100,000 children, respectively. The incidence rate increased from 0.2 in 2002 to 0.9 in 2006 (Z score of 39.87, \( p = 0.00 \)). The age at presentation ranged from 5 months to 14 years. Nine had Crohn's disease (6 males) and 6 had ulcerative colitis (4 males). One patient had indeterminate colitis. The most common clinical features were diarrhea in 10 (62.5%), abdominal pain, anorexia and weight loss in 9 (56.2%), anemia in 7 (43.75%) and vomiting in 6 (37%). Ileopancolitis was found in 3 patients whereas 6 patients had ileocecal disease. Conclusions: Childhood inflammatory bowel disease in this population is not so rare and it is increasing. The clinical pattern is similar to that reported by others.

Abbreviations: IBD= inflammatory bowel disease, CD= Crohn’s disease, UC= Ulcerative colitis, IC= Indeterminate colitis, GIT= gastrointestinal tract.

INTRODUCTION

Inflammatory bowel disease (IBD) includes a heterogeneous group of immunologically mediated inflammatory conditions of the gastrointestinal tract (GIT) with or without extraintestinal manifestations. Major members of this group are Crohn's disease (CD) and ulcerative colitis (UC). Both of these disorders are chronic diseases characterized by remissions and relapses. Crohn's disease can directly involve any part of the gastrointestinal tract, whereas ulcerative colitis involves only the colon. The clinical manifestations of Crohn's disease in particular are varied and include poor growth, abdominal pain, diarrhea, constipation, rectal bleeding, fever, and anaemia. Ulcerative colitis, on the other hand, is characterized by bloody diarrhea and abdominal pain among other symptoms. However, CD can present with colitic features similar to those of UC. Indeterminate colitis (IC) is another less common member of the group and its diagnosis rests on the exclusion of other causes of colitis. Some believe that it is a temporary stage towards the development of CD or UC [1]. However, others find it a clearly distinct member of the group [2].

The aetiology of IBD is still a mystery in spite of extensive research in the field. It is thought that environmental factors play an important role as evidenced by a relatively low concordance rate among identical twins. However, the higher frequency of IBD in first degree relatives indicates a role for genetics in its etiology [3].

Inflammatory bowel disease occurs with a variable frequency in different parts of the
world. It is a common observation that IBD is prevalent in industrialized countries as it is seen in Europe and USA but much less common in the southern part of the globe [4-6]. Twenty to twenty five percent of CD and UC cases, respectively, present during childhood [7].

Neither the prevalence of childhood-onset IBD nor its clinical profile has been described, and only a few reports have been published on IBD in Arab and Middle Eastern countries. These reports show that IBD is not common in this part of the world [8-10].

The importance of environmental factors in the development of IBD is further substantiated by the increasing frequency of IBD in areas that used to have a distinctly low prevalence [11]. Westernization of the life style in these areas is thought to be a contributing factor to this rise in IBD frequency in spite of lack of a hard causal relationship. We see in our practice that there has been an increase in the number of cases referred to us for possible IBD in the last decade. We therefore carried out a retrospective descriptive study on IBD in Eastern Libya to know the prevalence of childhood IBD and its clinical profile.

MATERIAL AND METHODS

A retrospective study was performed on the children diagnosed as having either CD or UC or indeterminate colitis (IC). Benghazi is the second major city in Libya and its hospitals function as referral hospitals for the rest of the eastern part of the country. As a rule, all children with suspected and/or diagnosed IBD are evaluated and followed up at the gastroenterology-hepatology clinic of Al-fateh Childrens’ Hospital (AFCH), which is a major teaching hospital and the only pediatric referral hospital in the whole eastern region. However, since some adolescents might as an exception looked after by adult physicians, we looked at the records of adult gastroenterology clinics in Benghazi area as well (one at El-Keish polyclinic and another one at Al-jamhouriya hospital). Inclusion criteria were as follows: presence of IBD, age <15 years at the time of presentation, presentation within the last 10 years (1997-2006), and residence in the east of Libya. More common differential diagnoses, such as amoebiasis, bacterial infections, tuberculosis and allergy, were for all practical purposes ruled out by conventional methods, such as stool examination, culture techniques, imaging, tuberculin testing, radioallergosorbent tests, elimination and challenge dietary maneuvers, and therapeutic trials, as needed.

The usual workout of these patients included history taking, clinical examination (including screening for signs of vitamin deficiency) and anthropometric assessment (height, weight and mid-upper arm circumference). Local growth charts were used to assess growth [12, 13]. Puberty was graded according to the well known Tanner’s staging [14]. All patients were subjected to the following investigations: full blood count, erythrocyte sedimentation rate (ESR), serum calcium, phosphorus, alkaline phosphatase and albumin, in addition to blood urea and serum creatinine. C-reactive protein and serum ferritin were done only in the more recent cases. The diagnosis was based on clinical, endoscopic, radiological and histopathologic findings. All patients were endoscoped, except for one in whom the diagnosis was based on post-operative histopathology of an excised ileocaecal mass. Data on the structure of the population were obtained from a census carried out in 2006 by the National Data and Documentation Bureau. According to this census, the annual growth rate over the period 1996-2006 is 1.83%. We used this figure to estimate the population size over the years of our study. Prevalence and incidence rates were expressed as the number of cases per 100,000 children under 15 years old. Results were expressed as ranges, means ± standard deviation (SD) and percentages. A z-test at a confidence level of 95% was used to test the statistical significance of any possible change in prevalence or incidence. EpiCalc-2000 version 1.02 software was used for this purpose.

RESULTS

The number of people aged < 15 years in the catchment area was 441,371. Sixteen patients had IBD giving a total prevalence and incidence rates of 3.6 and 0.9 per 100,000 in the year 2006, respectively. Fifteen patients were registered at AFCH and one at Al-jamhouriya hospital. The incidence rate increased 4-folds from 0.2 per 100,000/year in the year 2002 to 0.9 per 100,000/year in 2006 with a Z score of 39.87 (p= 0.00) (table 1). The prevalence rate increased from 1.2 per 100,000 in 2002 to 3.6 per 100,000 in 2006, with a Z score of 71.33 (p = 0.00). IBD prevalence in Benghazi governorate in the year 2006 was 6 per 100,000. Table 2 shows the individual prevalence rates of CD and UC in the studied governorates. Eleven of our patients were males (M:F ratio =1.5:1). The age at presentation ranged from 5 months to 14 years with a mean of 10.3 ± 2.8. Nine patients had CD (males =6) with a mean age of 8.3± 4.2 years (range: 9 months-14 years).
Six patients had UC (4 males) with a mean age of 8±4 years (range 2.5-13 years). One patient who was 5 months old at the time of presentation had indeterminate colitis. One patient was initially diagnosed as UC and few years later turned out to be CD. Time elapsed between onset of symptoms and diagnosis mostly ranged from 2 months to 4 years, but in one case this took 8 years.

* Values between brackets represent prevalence rates per 100,000 children

Diarrhea was the most common clinical feature and seen in 10 (62.5%) of IBD cases particularly in those with CD (77%). One patient with Crohn’s disease had constipation as a prominent chronic symptom. Anorexia, abdominal pain, weight loss and rectal bleeding were each found in 9 patients in various combinations. However, all patients with UC had rectal bleeding whereas just 3 out of 9 CD patients had it (100% vs 33%). Linear growth was impaired in 5 patients with pubertal delay in 2 of them. Perianal disease including fistulas, abscesses, tags and nodules was seen in 4 CD patients (44% of Crohn’s). Well
defined extraintestinal manifestations were seen in one patient in the form of mono-articular arthritis and the same patient had extensive aphthous ulceration of the mouth. Less well defined symptoms such as arthralgias and muscle pains were seen in four IBD patients. Two patients were subjected to operation for a right iliac fossa mass. Three patients with CD and one with UC were classified as having severe illness.

**INVESTIGATIONS** Hemoglobin level at presentation ranged from 7-13.5 (10.4±1.75) gm/dl. Anaemia at presentation was found in seven patients (43.8%). ESR was high in 7 out of all patients and C-reactive protein in 2 out of 7 cases subjected to the test. All UC patients had distal colitis. The localization of the disease among CD patients was as follows: ileoanocolitis in 3 and ileocecal in 6. Two patients have upper GIT involvement. Five patients were given multiple empirical treatments for amebiasis prior to referral to our hospital. None of these patients was investigated before receiving the anti-amoebic treatment.

**TREATMENTS** In addition to supportive therapy patients were treated with systemic steroids, salazopyrine, 5-ASA derivatives and metronidazole in various combinations. Azathioprine was used for 3 patients. Budesonide enema was highly effective in 3 patients with colitis. Nutritional defined formula was available for use only on 2 occasions.

**DISCUSSION** We show that juvenile onset IBD is not so rare in the eastern part of Libya, with a prevalence rate of 3.6 per 100,000 in 2006. Though our clinic at AFCH looks after most children with suspected and/or diagnosed IBD, we can not assume that all IBD cases are referred to AFCH, particularly those with milder forms of the disease. However, even on keeping this limitation in mind the prevalence and incidence rates of IBD are obviously lower than the rates in Western countries, where rates of 2.2-7/100,000 per year were reported [15-18]. A similar study from Saudi Arabia reported a prevalence of 5 per 100,000 [10] which is quite similar to ours. In addition, another study from Saudi Arabia pointed to a low rate of IBD, though no exact prevalence figures were reported. In their report, Isbister and Hubler described just 101 IBD cases from Saudi Arabia during almost two decades (1976-1994) [19]. A relative exception to this comes from a study on adult Kuwaiti patients, in which 91 patients with UC and 14 with CD were diagnosed over 6 years in a hospital serving 55% of the population of Kuwait [20]. The authors in this study suggested that IBD is likely to be common in Kuwait.

Eastern Libya is characterized by having a more ethnically homogeneous population than that encountered in most of the Gulf countries which may account, at least partially, for the observed differences in prevalence rates. However, rest of Libya is ethnically less homogeneous and our results might not be applicable to the rest of it. Though most Libyans are of Arab ancestry, some have African roots, particularly in the south of the country. Ethnic heterogeneity in the epidemiology and phenotype of IBD is well known. For example, ethnic differences have been observed in the multiracial Asian countries. In addition, NOD2/CARD15 variants have not been found in Asian CD patients, indicating a different genetic background from Western CD patients [11]. The effect of race extends to involve the phenotype of IBD. In a report on characteristics of IBD among African Americans, Hispanics and non-Hispanic whites in north America, African American CD patients were more likely to have gastroduodenal, colorectal and perianal disease and less likely to have ileal involvement [21]. Some European countries reported a relatively low incidence of IBD in children [18]. From the above we could see that the rates of occurrence of IBD have no consistent pattern among western countries and it would be an oversimplification to generalize statements on the prevalence of IBD in developed and under-developed areas of the world.

The prevalence of IBD has been increasing in western and non-western countries [10,22,23]. Since our clinic is for all practical purposes the only one looking after pediatric IBD cases in the eastern part of Libya, we have the unique position of knowing most children with IBD in our area. We had the impression that IBD locally is increasing. Our study showed that the incidence of IBD has increased fourfold in 2006 compared to 2002. We feel that this increase in the occurrence rate is most probably a real one since the diagnostic facilities have not changed much over these 5 years. This rise in occurrence might be a result of the westernization of the local life style. It has been observed that IBD incidence has increased in urban areas [24]. Urbanization of lifestyle embodies changes in diet and environment. For example, non-nutritive
microparticles such as titanium dioxide are found in the diet. These microparticles are believed to combine with other substances found in the intestine to form antigens capable of mediating inflammatory immune responses. Patients with IBD were also shown to consume higher amounts of sucrose and refined carbohydrates [25]. Table sugar is subsidized by the Libyan government, resulting in high consumption rates. Such dietary changes might have contributed to the observed rise in IBD incidence in our area. On the other hand, IBD is more likely to occur in people exposed to dirt and helminthes [26,27]. However, we cannot eliminate the possibility of increased awareness of the disease as a contributing factor to the rise in the incidence.

Though AFCH is the only hospital at which young children from eastern Libya with suspected IBD are evaluated, we cannot claim that every child with IBD is referred to us. It is possible that some patients did not find their way to us either because of less awareness of the disease in governorates other than Benghazi or because they managed to get medical advice in nearby countries. For all these reasons, it is likely that the actual prevalence and incidence figures are higher than those we got.

Interestingly, the prevalence rates of CD and UC in Benghazi were equal (3 per 10^5). This is in contrast to reports from western countries which show that UC is significantly more common [18,22]. This opposite trend is increased further if we include patients from other governorates where CD outnumbers UC. It is known that dietary factors and intestinal microflora play an important role in IBD. The different dietary habits prevalent locally and the higher rate of early childhood infections might have something to do with this difference between ulcerative colitis and Crohn’s disease [28]. The predominance of UC is not universal in industrialized countries. A report from France shows predominance of CD over UC, a trend similar to ours. However, because of the small number of cases in our study we stress that such comparisons need to be taken with caution.

The clinical features of Crohn’s disease and ulcerative colitis in the Libyan patients were similar to those reported from western and non-western countries. Common presenting features in our patients were diarrhea, abdominal pain, weight loss, anorexia and bleeding. A study carried out on presenting features of IBD in Great Britain and Ireland showed a very similar pattern to ours [29]. This was somewhat unexpected finding in view of our small sample size and in view of the epidemiological differences between these European countries and Libya. Table 3 compares our finding with theirs.

Because IBD in Libya is considered by the local medical community as a rare disease, doctors tend to label patients with more common diagnoses. In this cohort, 5 patients received blind treatment for amebiasis on a number of occasions. Such an empirical treatment might delay the diagnosis particularly if metronidazole is used. Though it is crucial to rule out more common diseases in developing countries, it is important not to miss IBD. Tuberculosis is seen in Libya more frequently nowadays than it was a decade ago and it has to be kept in mind as a differential diagnosis. Recently, a group of pediatric gastroenterologists released a report on the criteria for diagnosis of IBD. In this report, it was stressed that every child suspected of having IBD should be subjected to a complete
diagnostic work up. This work up is composed of history, clinical examination, ileocolonoscopy, upper GIT endoscopy and in all cases a contrast small bowel study (with possible exception of obvious ulcerative colitis) [30]. Understandably, these recommendations are universal and need to be implemented locally as well.

In conclusion, we have shown that juvenile onset IBD is not that rare in Libya and its clinical features resemble those reported in other countries. It is also clear that childhood IBD is on the rise in Libya. Though it is important to exclude common infections, it is crucial to keep the possibility of IBD in mind. Studies on juvenile onset IBD in other parts of the country are highly needed as well.
