Abstract

Background
Severe anemia is a major cause of sickness and death in African children, yet the causes of anemia in this population have been inadequately studied.

Methods
We conducted a case–control study of 381 preschool children with severe anemia (hemoglobin concentration, <5.0 g per deciliter) and 757 preschool children without severe anemia in urban and rural settings in Malawi. Causal factors previously associated with severe anemia were studied. The data were examined by multivariate analysis and structural equation modeling.

Results
Bacteremia (adjusted odds ratio, 5.3; 95% confidence interval [CI], 2.6 to 10.9), malaria (adjusted odds ratio, 2.3; 95% CI, 1.6 to 3.3), hookworm (adjusted odds ratio, 4.8; 95% CI, 2.0 to 11.8), human immunodeficiency virus infection (adjusted odds ratio, 2.0; 95% CI, 1.0 to 3.8), the G6PD-202/176 genetic disorder (adjusted odds ratio, 2.4; 95% CI, 1.3 to 4.4), vitamin A deficiency (adjusted odds ratio, 2.8; 95% CI, 1.3 to 5.8), and vitamin B deficiency (adjusted odds ratio, 2.2; 95% CI, 1.4 to 3.6) were associated with severe anemia. Folate deficiency, sickle cell disease, and laboratory signs of an abnormal inflammatory response were uncommon. Iron deficiency was not prevalent in case patients (adjusted odds ratio, 0.37; 95% CI, 0.22 to 0.60) and was negatively associated with bacteremia. Malaria was associated with severe anemia in the urban site (with seasonal transmission) but not in the rural site (where malaria was holoendemic). Seventy-six percent of hookworm infections were found in children under 2 years of age.

Conclusions
There are multiple causes of severe anemia in Malawian preschool children, but folate and iron deficiencies are not prominent among them. Even in the presence of malaria parasites, additional or alternative causes of severe anemia should be considered.

Introduction
Severe anemia (hemoglobin concentration less than 5.0 g per deciliter) is a major cause of sickness and death among children in sub-Saharan Africa.1,4 In various settings, 12 to 29% of hospitalized children are severely anemic,1,4 and the in-hospital case fatality rate in these children is 8 to 17%.1,3,4 Little is known about the causes of severe anemia in African children. Most studies have been confined to the anemia associated with malaria or with other individual factors.2,3,6 As a result, the treatment guidelines advocated by the World Health Organization (WHO) deal specifically with malaria, folate deficiency, and iron deficiency, which are widely held to be the most common causes of severe anemia in African children.7 To improve our understanding of severe anemia, we conducted a case–control study in Malawi to assess the causative factors in Malawian children with severe anemia.

Methods
Study sites
We conducted the study in Malawi at Chikwawa District Hospital in a rural area where malaria infections occur throughout the year (approximately 170 infectious bites per person per year) and at Queen Elizabeth Central Hospital, a referral hospital in urban Blantyre, where malaria is seasonal, largely coinciding with the rainy season (approximately 1 infectious bite per person per year) (Mzilahowa T: personal communication). Predefined catchment areas were used; the urban area was confined to the city limits.

Study design
Between July 2002 and July 2004, a consecutive sample of children (382 case patients) who presented at the outpatient department during working hours with a primary diagnosis of severe anemia (defined as a hemoglobin concentration of <5.0 g per deciliter) were recruited into a prospective case–control study. Additional inclusion criteria were an age between 6 and 60 months and no blood transfusion within the previous 4 weeks.

For each case patient, a community control patient and a
hospital control patient were enrolled. Community control patients were recruited from apparently healthy residents living within 100 to 1000 m of the case patient; hospital control patients were recruited by selecting the first child presenting at the outpatient department at the same time on the next working day after presentation of the case patient. Community and hospital control patients were eligible for recruitment if their hemoglobin level was at least 5.0 g per deciliter and they were between 6 and 60 months of age; no other matching was applied. Written informed consent was obtained from a parent or a guardian of each child in all three study groups. The study was approved by the ethics committees of the College of Medicine, Malawi, and the Liverpool School of Tropical Medicine, United Kingdom.

**Clinical assessment and management**

On enrollment, a clinical research form, including a medical and dietary history, sociodemographic data, and physical examination, was completed, and samples of blood, urine, and stool were collected. In case patients, if the clinical condition permitted it, a bone marrow aspirate was obtained under local anesthesia. Children requiring admission were treated in a study ward. All conditions were managed according to standard protocols.

**Anthropometric measurements**

Nutritional z scores were calculated according to the WHO growth reference curves\(^8\) with the use of Epi Info 2000. Weight-for-height, height-for-age, and weight-for-age z scores of less than –2 were considered to indicate wasting, stunting, and underweight, respectively; z scores of less than –2 were considered to indicate severe wasting, severe stunting, and underweight, respectively; z scores of less than –3 were considered to indicate severe wasting, severe stunting, and underweight, respectively.

**Laboratory methods**

Laboratory tests (hematologic, bacteriologic, and parasitologic) were performed within 24 hours after collection, and aliquots were stored at –80°C for later analysis. The laboratory staff were unaware of the children's study groups.

**Hematologic studies**

Hemoglobin concentration was measured on site with a HemoCue system. A complete blood count, including reticulocytes, was performed by a Coulter counter. In case patients, bone marrow slides were stained with Hematognost Fe (Merck) and graded for iron content\(^9\); these results were used to validate peripheral blood markers of iron deficiency. The ratio of soluble transferrin receptor to log ferritin (TfR-F index)\(^10\) best predicted bone marrow iron status, irrespective of the presence of infection; a TfR-F index greater than 5.6 was used to define iron deficiency with a sensitivity of 70% and a specificity of 75% (unpublished data).

**Chemical studies**

Plasma levels of C-reactive protein, haptoglobin, transferrin, iron, ferritin, folate, and vitamin B\(_12\) were analyzed on Modular P800 and Modular Analytics E170 systems (Roche). Inflammatory cytokine profiles were measured by Cytometric Bead Array on a FACSCalibur flow cytometer (Becton Dickinson). Serum vitamin A (retinol) and soluble transferrin receptor were measured by high-performance liquid chromatography\(^11\) and enzyme-linked immunosorbert assay, respectively.

**Parasitologic Studies**

The number of *Plasmodium falciparum* asexual parasites per 200 white cells was counted and expressed as the number per microliter of blood. Malaria slides were read by two independent readers, with a third being used if the results differed by more than 25%. Malaria was defined by the presence of *P. falciparum* asexual parasites. Recent or current malaria was defined by the presence of *P. falciparum* asexual parasites in erythrocytes or malaria pigment in monocytes or macrophages.\(^12\) Hyperparasitemia was defined as more than 100,000 parasites per microliter.\(^3\) Stool samples were examined for helminths by the Kato–Katz method.\(^13\) Heavy hookworm infection was defined by the presence of more than 1000 ova per gram of feces. A polymerase-chain-reaction (PCR) test was used to confirm the microscopical results and define the species (*Ancylostoma duodenale* or *Necator americanus*).\(^14\) Urine specimens were examined for *Schistosoma haematobium* by a semiquantitative concentration method.\(^15\)

**Bacteriologic studies**

A bone marrow or venous blood sample (1 to 2 ml) was inoculated into BACTEC Myco/F-Lytic culture vials and incubated in a BACTEC 9050 automated culture system (Becton Dickinson) for 56 days. Subculturing, susceptibility testing, and isolate identification were performed by standard techniques.\(^16\) Cultures were checked for mycobacteria with the use of Ziehl–Neelsen staining of smears. Mixed growths or growths of micrococci, bacillus species, or coagulase-negative staphylococci were considered contaminants.

**Virologic studies**

Whole-blood isolates\(^17\) were assessed for Epstein–Barr virus and cytomegalovirus infection by semiquantitative PCR\(^18\) and for parvovirus by real-time PCR.\(^19\) Infections were considered clinically important if the number of viral copies exceeded 1000 per milliliter of blood. Testing for human immunodeficiency virus (HIV) was performed by two rapid tests (Determine, Abbott Laboratories; and Uni-Gold, Trinity Biotech). Discordant or positive rapid-test results in children less than 18 months of age were resolved by PCR.\(^20\)

**Genetic studies**

DNA was extracted with a Nucleon extraction kit (Amersham Biosciences) and genotyped by primer-extension mass spectrometry with the use of MassARRAY (Sequenom).\(^21\) The presence of sickle cell disease (hemoglobin S) and single-nucleotide polymorphisms in the promoter regions of the genes encoding interleukin-10 (IL10) (–1117, –3585, and +4949)\(^22\) and tumor necrosis factor (TNF) (–238, –308, and –1031)\(^23\) was determined. The term G6PD\(_{202/376}\) is used to denote boys who are hemizygous and girls who are homozygous for both the G6PD\(_{202}\) and G6PD\(_{376}\) alleles, a condition that is strongly predictive of glucose-6-phosphate dehydrogenase deficiency.\(^24\) The Hardy–Weinberg equilibrium was applied (cutoff, P<0.001), and there was no significant population stratification. We chose the allele frequency, dominant model, or haplotype that was most strongly associated with severe anemia.

**Statistical analysis**

The prevalence rates of each factor were compared individually across the three groups with the use of Fisher's exact test and the chi-square test. The combined association of characteristics related to the risk of severe anemia (P≤0.10, unless the characteristics were uncommon [<5%]) was examined by an unconditional multivariate logistic-regression model corrected for potential confounding.
Factors (age, sex, recent use [i.e., within the previous 8 weeks] of antimalarial or hematocinic agents, and a history of transfusions [i.e., before the previous 4 weeks]). Missing observations were included in the analysis by creating missing-value categories. Alternative definitions for malaria, hookworm, and nutritional deficiencies and status were tested. Attributable-risk percentages were calculated with the use of adjusted odds ratios. The primary analysis compared all case patients with the two control groups combined. To explore the possibility that different patient characteristics were important in the two study locations, secondary analyses were performed with stratification according to location and with the community and hospital control groups separated. More complex associations and alternative strategies for handling missing data (e.g., maximum-likelihood imputation) were explored by structural equation modeling. All reported P values are two-sided. The data were analyzed with the use of Stata (version 9), SPSS (version 12), and Amos (version 6.0) software.

Results

We enrolled 1141 children over a 2-year period. Five protocol violations occurred: two hospital control children had severe anemia and were redesignated as case patients, one case patient with a hemoglobin concentration of more than 5.0 g per deciliter was excluded, and two control patients under 6 months of age were excluded. Table 1 summarizes the characteristics of the 1138 children included in the analysis.

Table 1. Characteristics of the Study Groups.
In the rural setting, a significant association between malaria and severe anemia was found only in the subgroup of patients who had hyperparasitemia (9.7%) (adjusted odds ratio for severe anemia associated with HIV was 6.2% overall and 15.4% in the urban setting. Among severely anemic children, significantly more HIV-infected than HIV-uninfected children had Epstein–Barr virus infection (15 of 30 [50.0%] vs. 69 of 226 [30.5%], P = 0.03) or bacteremia (11 of 42 [26.2%] vs. 38 of 300 [12.7%], P = 0.02), whereas significantly fewer HIV-infected than HIV-uninfected children had hyperparasitemia (2 of 44 [4.5%] vs. 42 of 312 [13.5%], P = 0.09) or vitamin B₁₂ deficiency (5 of 39 [12.8%] vs. 85 of 254 [33.5%], P = 0.009).

**Bacteremia**

Fifty-four case patients (15.0%) and 14 controls (4.0%) had bacteremia. The attributable risk of severe anemia associated with bacteremia was 12.2%. The most common pathogen...
Severe anemia in Malawian children

Vitamin B12 deficiency was found in 95 case patients (30.4%) and 94 controls (15.6%) and was severe (<13.6 ng per deciliter [100 pmol per liter]) in 11.2% of case patients and 2.8% of controls (adjusted odds ratio, 4.3; 95% CI, 1.9 to 9.9). Macrocytosis was more common in children with vitamin B12 deficiency than in children with normal vitamin B12 levels (P=0.02), although the sensitivity for vitamin B12 deficiency was low (17.5%). Severely anemic children with vitamin B12 deficiency ate fewer meals with meat than those not deficient (1.9 vs. 2.7 per month, P=0.02). Folate deficiency was not found in any child enrolled in the study. Vitamin B12 and folate levels were inversely correlated with each other among severely anemic children (Pearson correlation coefficient, −0.22; P=0.01).

Vitamin A deficiency was found in 92.3% of case patients and 65.6% of controls and was considered severe (less than 10 μg per deciliter) in 32.8% of case patients and 14.9% of controls (adjusted odds ratio, 1.6; 95% CI, 0.91 to 2.76). Vitamin A deficiency was associated with malaria and bacteremia in the structural equation model. Iron deficiency was found to be inversely associated with vitamin A deficiency ate fewer meals with meat than those not deficient (1.9 vs. 2.7 per month, P=0.02). Folate deficiency was not found in any child enrolled in the study. Vitamin B12 and folate levels were inversely correlated with each other among severely anemic children (Pearson correlation coefficient, −0.22; P=0.01).

Vitamin A deficiency was found in 92.3% of case patients and 65.6% of controls and was considered severe (less than 10 μg per deciliter) in 32.8% of case patients and 14.9% of controls (adjusted odds ratio, 1.6; 95% CI, 0.91 to 2.76). Vitamin A deficiency was associated with malaria and bacteremia in the structural equation model. Vitamin A deficiency was associated with malaria and bacteremia in the structural equation model. Iron deficiency was found to be inversely associated with vitamin A deficiency ate fewer meals with meat than those not deficient (1.9 vs. 2.7 per month, P=0.02). Folate deficiency was not found in any child enrolled in the study. Vitamin B12 and folate levels were inversely correlated with each other among severely anemic children (Pearson correlation coefficient, −0.22; P=0.01).
Hookworm

Hookworm was the most common helminth infection. Thirty-one (75.6%) of the hookworm infections occurred in children less than 2 years old. The attributable risk of severe anemia associated with hookworm in the rural site, where 95.1% of infections were seen, was 15.9%. In this site, 10.4% of case patients and 0.6% of controls had heavy infections (adjusted odds ratio, 9.4; 95% CI, 2.0 to 44.8). PCR was performed on 36 of 41 positive samples (87.8%). *A. duodenale* was found in 80.6% of these samples, *N. americanus* in 8.3%, and a mixed infection in 11.1%. Hookworm infection was associated with iron deficiency (P=0.003) (Figure 2).

Sickle cell and G6PD variants

No association was found between severe anemia and sickle cell disease or between severe anemia and sickle cell trait (P=0.45 and P=0.20, respectively). Jaundice was uncommon in severely anemic children with sickle cell disease (9%) or G6PD-202G (2.3%). Haptoglobin levels were commonly decreased (≤0.30 g per liter) in case patients with G6PD-202G (78.4%). Boys accounted for 68.2% of children with G6PD-202G, but after stratification, G6PD-202G remained significantly associated with severe anemia in girls (adjusted odds ratio, 4.1; 95% CI, 1.2 to 13.3) and boys (adjusted odds ratio, 2.2; 95% CI, 1.1 to 4.7).

Discussion

In many African hospitals, severe anemia is a leading reason for admission and a major contributor to death. The cause of the anemia has not been comprehensively investigated, but we found several important associations in this study. Malaria is commonly considered to be a principal cause of severe anemia in Africa. In this study, *P. falciparum* parasitemia was strongly associated with severe anemia in the area with seasonal transmission but not in the area with holoendemic transmission. However, the cumulative effect of malaria on an individual person is difficult to assess in holoendemic settings where children are repeatedly infected. Our findings therefore do not exclude malaria as a predisposing cause of severe anemia in the rural area but indicate that additional or alternative diagnoses should be considered in severely anemic children who receive a diagnosis of malaria infection. In the structural equation model, malaria and bacteremia were more strongly associated with severe anemia in the area with seasonal transmission but not in the area with holoendemic transmission.

The model was corrected for the possible confounders of age, sex, recent antimalarial treatment (within the previous 8 weeks), recent hematinic treatment (within the previous 8 weeks), a history of transfusion (before the previous 4 weeks), and death of a parent. The relative risk of severe anemia associated with severe anemia decreased (<0.30 g per liter) in case patients with (P=0.45 and P=0.20, respectively). Jaundice was uncommon. No association was found between severe anemia and sickle cell and G6PD variants. Sickle cell and G6PD-202G were identified in 226 case patients and 6.0% of controls. The attributable risk of severe anemia associated with malaria and bacteremia was identified in 226 case patients and 6.0% of community controls, 7.1; 95% confidence interval [CI], 1.4 to 34.6). In the combined model, interaction existed between severe anemia and sickle cell variants, and a mixed infection in 11.1%. Hookworm infection was found in 80.6% of these samples, *N. americanus* was found in 80.6% of these samples, and a mixed infection in 11.1%. Hookworm infection was associated with iron deficiency (P=0.003) (Figure 2).

The reference single-nucleotide polymorphism (rs) classification for *IL10* +4949 (G/G) was less than 5%. The reference single-nucleotide polymorphism (rs) classification for *G6PD* A. duodenale and *P. falciparum* was identified in 226 case patients and 6.0% of controls. In this site, 10.4% of infections were seen, was 15.9%. In this study, 10.4% of case patients who had hyperparasitemia of less than 20 ng per deciliter (148 pmol per liter) and of vitamin A were less than 20 μg per deciliter (0.7 μmol per liter) are considered to indicate deficiency. Iron deficiency is defined as a ratio of soluble transferrin receptor to log ferritin (TFR:F index) of more than 5.6 (unpublished data). Cultures to detect bacteremia were performed only in case patients and hospital controls. Hookworm infection was not entered in the urban model because the prevalence remained less than 5%. The reference single-nucleotide polymorphism (rs) classification for *IL10* +4949 is rs3024500. Because of the high correlation among the three interleukin-10 polymorphisms, only one (most strongly associated with severe anemia) was included in the multivariate model. HIV denotes human immunodeficiency virus, and G6PD-202G denotes boys who are hemizygous and girls who are homozygous for both the G6PD202G and the G6PD376G alleles.

![Figure 1. Adjusted Odds Ratios and 95% Confidence Intervals for Factors Associated with Severe Anemia, According to Study Group and Recruitment Site.](http://dx.doi.org/10.1056/NEJMoa0702272)
We found an inverse association between iron deficiency and severe anemia. The structural equation model partly explains this finding by indicating that iron deficiency was inversely associated with bacteremia. This finding supports the hypothesis that iron deficiency protects against infection by creating an unfavorable environment for bacterial growth.\textsuperscript{31,32} It is also in agreement with observations of increased morbidity and mortality during iron-supplementation studies in areas where bacterial infections are common.\textsuperscript{33,34} Although iron supplementation may have a role in preventing anemia,\textsuperscript{33} supplementation after severe anemia of malaria had no hematologic benefits and resulted in increased morbidity in Tanzanian children.\textsuperscript{34}

In rural children with severe anemia, we found an increased prevalence and intensity of hookworm infections, with \textit{A. duodenale} being the predominant species. Three quarters of the hookworm-infected children were less than 2 years of age. This age group would have remained untreated according to the current guidelines.\textsuperscript{7} Although hookworm is usually more frequent among older children, younger children might be more vulnerable to severe hematologic complications, especially in the presence of heavy infections with \textit{A. duodenale}.\textsuperscript{35}

Bacteremia, most commonly due to nontyphoid salmonella, was strongly associated with severe anemia. This association has been described previously\textsuperscript{16,36,37} but is not reflected in current management guidelines for severe anemia in children.\textsuperscript{7} In the structural equation model, bacteremia was also identified as a mediating variable of the effect of HIV on severe anemia. Although bacteremia might not necessarily be a cause of severe anemia, its high prevalence may justify antibiotic treatment in the standard management of severe anemia in settings where HIV is prevalent and blood-culture facilities are not available.

Although folate supplementation is recommended by the WHO, folate deficiency was not found in our study groups. We may have underestimated its prevalence, because folate deficiency can be masked by vitamin B\textsubscript{12} deficiency,\textsuperscript{38} and we measured plasma concentrations of folate rather than erythrocyte concentrations. However, our findings concur with previous reports\textsuperscript{39} and observations that folate supplementation in anemic children with malaria failed to raise hemoglobin concentrations.\textsuperscript{40} Unlike folate, vitamin B\textsubscript{12} is not recommended in the management of severe anemia. In our population, vitamin B\textsubscript{12} deficiency was found in 30.4% of case patients and was associated with severe anemia. This is in agreement with findings among adults in this region\textsuperscript{41,42} and may be explained by the lack of animal products in the diet of Malawian children.

\textit{G6PD}\textsuperscript{202/376} was found in 13.8% of case patients and was associated with severe anemia, whereas sickle cell disease was uncommon in our study. The roles of these mutations may be different in West and Central Africa. Possible associations of interleukin-10 and tumor necrosis factor \textgamma with severe anemia of malaria have been described,\textsuperscript{43,44} but in our study an imbalance in circulating plasma levels of interleukin-10 and tumor necrosis factor \textgamma was uncommon.

We found that several independent yet overlapping conditions are associated with severe anemia in Malawian children: bacteremia, malaria, hookworm, HIV infection, \textit{G6PD}\textsuperscript{202/376}, vitamin A deficiency, and vitamin B\textsubscript{12} deficiency. Our findings indicate that even in the presence of malaria parasites, additional or alternative diagnoses should be considered. Current treatment recommendations that promote iron and folate supplements and ignore bacteremia, vitamin B\textsubscript{12} deficiency, and, in young children,
hookworm infections appear to be of limited applicability in our setting. Our findings, if confirmed in different settings, will contribute to the assessment of new therapeutic and preventive strategies for Africa.

Supported by a grant (064722) from the Wellcome Trust and by independent grants from the Nutricia Research Foundation and the Ter Meulen Fund of the Royal Netherlands Academy of Arts and Sciences.

No potential conflict of interest relevant to this article was reported.

We thank the parents and guardians of the children admitted to the study; the Severe Anemia (SevAna) study team; and the staffs of the Queen Elizabeth Central Hospital, the Chikwawa District Hospital, and the Wellcome Trust Research Laboratories, especially S.M. Graham, E.M. Molyneux, T.N. Williams, M. Cornelissen, H. van den Berg, R.J.W.M. Vet, Z. Ayle, A. van Breda, J.J. Verweij, B.J.E. van Geenen, M.A. Sanjoaquin, R.J. Kraaijenhagen, F.A. Wijnberg, and W.J. van Lüling, for their contribution to the study.

* Other markers that were assessed but not presented because they predicted iron deficiency less well (with sensitivity, specificity, or both under 40%) were ferritin, transferrin receptor, serum iron, serum transferrin, total iron-binding capacity, and transferrin saturation. CI denotes confidence interval, CRP C-reactive protein, and TFR-F index the ratio of soluble transferrin receptor to log ferritin.
† The odds ratios were obtained by replacing the original variable for iron deficiency in the multivariate analysis with the alternative definition.
‡ The original definition of iron deficiency was a TFR-F index greater than 5.6.
§ Iron deficiency is defined as a CRP-containing index (0.34 + 0.0043 × ferritin − [2.7 × TfR] ÷ ferritin + 0.0696 × CRP + 0.05 × TfR) of less than 0.26.
¶ Microcytosis is defined as a mean corpuscular volume of less than 76 fl in children under 2 years of age and less than 73 fl in children 2 to 5 years of age.27
§ Hypochromasia is defined as a mean corpuscular hemoglobin concentration of less than 32 g per liter.27
