SUMMARY
Background: Enugu State typifies a Third World environment where most deliveries occur outside the hospital setting. In such circumstances, hospital-based data about congenital defects are unreliable and call for special methods of approach.

Objective: To determine the prevalence and pattern of male external genital defects in Igbo male secondary school students in Nigeria.

Method: Samples of male students aged 10 years and above seen in randomly selected secondary schools in Enugu State, of South-East Nigeria were guided through a protocol involving, self administered questionnaires, personal interviews and physical examinations for evidence and types of anomalies present in their external genitalia. The participating schools were selected by stratified random sampling; first by local government Areas (L.G.A) and then by schools. Consents for the study were obtained from Local Government Authorities, Heads of the schools and Parents' Teachers Associations, (PTA) Executives.

Results: Altogether, four urban and thirteen rural schools were studied, and a total of 6225 male students participated. Overall, 416 (6.8%) were identified with various types of external genital anomalies, with the prevalence observed being within the ranges of population prevalence reported in the literature. The commonest types of anomalies encountered were crypto-orchidism with / or without scrotal hypoplasia 268 (4.30%), inguino- scrotal 56 (0.90%), and hydrocoele 52 (0.83%). As many as 183 (44%) of those with congenital genital defects were not aware that they had them.

Conclusion: External male genital defects among Igbos appear to be within the prevalence rate reported in the literature. However the ignorance rate of such defects is high within the Igbo society.

Key words: - Anomalies, male genitalia, prevalence. (Accepted 14 August 2006)

INTRODUCTION
Several kinds of developmental defects of the external male genitalia have been described in literature,12; the incidence of which differ from place to place. Their severities have ranged from life threatening to mere cosmetic distortions. Abnormal development involves both male and female genitalia alike and genetic, environmental, and hormonal causes have been identified 13-7. As opposed to genetic causes environmental causes usually have effects that are localized in a place and are, therefore, more readily identified and targeted for possible prevention,8-10. An essential step towards identification of an environmental cause is to study the pattern for possible identification of clustering of such anomalies. Most of the available epidemiological data about the incidence of genital defects are hospital based. However such incidence data are unreliable in countries such as Nigeria where most deliveries occur outside hospitals. Besides, superstitious beliefs abound concerning genital examination that often hampers community survey.11-11. Some of these anomalies are treatable especially when detected on time. If uncorrected, some of them could manifest as profound socialpsychological, medical, and marital complications in adult life,12-14. Early detection and correction of male organ abnormalities are, therefore, important not only for aesthetics but also for normal psychosocial and physical development of the affected children.
Some of the reasons proffered for late detection of external male genital defects are ignorance, religious and cultural inhibitions about sexuality, denial, false beliefs and alternative health care-seeking behavior, 11, 15, 16. Enugu State is one of the Igbo speaking states of Nigerian South-East. In traditional Igbo culture sexuality is a taboo topic 15. Studies about congenital genital defects are difficult among people with severe cultural or religious inhibitions about sexuality, 15. This is even more difficult among people in country such as Nigeria where traditional birth attendants with no iota of knowledge about congenital anomalies deliver more pregnant women than trained obstetricians. In the current study an attempt was made at elucidating the prevalence and pattern of external male genital defects among Igbo Nigerians, using the secondary school setting as a model. The awareness about developmental defects of the external male genitalia in this culture was also assessed.

SUBJECTS AND METHODS
Boys aged 10 years and above in randomly selected schools in Enugu -State, South - East Nigeria were studied. This study spanned over a period of 18 months between February 2 2002 and August 1 2004. There were 17 local government arrears in Enugu state and the number of schools per local government varies. In all there were about 107 government approved secondary schools in the state.

Sampling Methods
A cluster of random 3 - stage sampling technique was used.
First, 12% of local government areas in Enugu were randomly selected by process involving lot picking. Second, in the selected local government areas (LGAs), an exhaustive sample frame work of all the government approved secondary schools was obtained from the state's Ministry of Education. From these samples, at least 10% of these registered schools were selected for the study. Third, in each school so selected, all the male students aged 10 years and above who agreed to participate were recruited into the study. Efforts were made to elucidate the reasons for those who did not participate. The ages of the children were determined by their date of birth as recorded in the school registers which also gave their different classes. Each person recruited into the study passed through at least two of the three possible stages. First all the participants completed a structured, pre-tested and self-administered questionnaire embedded with color photographs of normal and abnormal external male genitalia. Information sort in this questionnaires included general knowledge about genital defects, (25%), the major sources of such information, (mother, father, parents, peers, school teachers, and others), and the participants ability to correctly identify and classify own genitalia as normal or abnormal. The second stage involved the clinical physical examination of the individual students (in a phantom make - shift clinics within accommodations provided by each of the schools' authorities.) in the presence of the various class teachers. This stage of the study included a general physical examination followed by detailed meticulous examination of the external genitalia including a determined search for lower anterior abdominal wall hernias. In third stage, all the participants who, on clinical ground were found to have external genital defects, were further interviewed in greater details. Another pre-tested interviewer-administered, 25-question questionnaire was administered. This stage involved details of all types of medical interventions so far sought by the candidates, or either of their parents or both. The parents of the children passing through this third stage were traced to their homes and interviewed, collecting information regarding to their level of awareness, beliefs, as well as their plans as regards to the future of their child vis- a - vis the defects detected. These parents were also educated on their children's external genital defects and advised on the prospects for remedy and prognosis. It will be noted that some of the students refused to participate in the study for personal reasons, while others could not participate because they were absent from school during the period the study was carried out in their own school. The reasons for their absence could not be elicited. However the percentage of those who did not participate judging by the class / school registers was not significant. Although the number was ignored, it was possible some few cases might have been missed but this might not have seriously affected the outcome of the study.

Statistical Methods:
The statistical analysis was carried out using Statistical Package for the Social sciences, (SPSS), computer software Version 11. The data were expressed as percentages, (%), and Medians, (Range), and were compared using Chi-Square Test and Wilcoxon's rank sum tests respectively for binary and discrete data. Association between awareness scores, and the other variables studied, (including their interactions), were explored by employing Chi Square analysis for trends, Kruskal- Wallis ANOVA and Spearman's correlation analysis as appropriate.
RESULTS
A total of 6226 subjects participated in the survey. Their ages ranged from 9 years to 23 years with a mean of 12.95 years. Only 7.71% of the participants were aged 5 to 11 years. Out of all the 6226 participants, 416 had evidence of defects in their external genitalia, giving an overall prevalence of 6.7%. Table 1 shows the pattern of anomalies observed. The commonest types of anomalies encountered were crypto-orchidism with and/or without scrotal hypoplasia (4.30%), inguinal (or scrotal) hernias 56 (0.90%), and hydroceles 54 (0.83%). Genital defects were more frequent in rural than urban schools (8.4% vs. 2.8% respectively; χ² = 58.35; p < 0.0001). Fig. 1 shows the frequency distribution of general awareness scores among the participants. Each of the questions answered correctly was scored 4% while wrongly answered questions were scored 0% each. The score for general awareness was 46.72% (0%–100%). One hundred and eighty-three of the subjects found with the genital defects were completely unaware of their anomalies, a case-ignorance rate of 44.0%. The level of case ignorance about genital defects was found to be more in rural than urban schools [84.6% vs. 51.4%; χ² = 4.83; p = 0.028], despite the higher frequency of cases found in the former. Of all the subjects from urban schools who were found with anomalies, 44 (84.6%) had had some form of medical intervention as against 5 (0.01) from rural schools [p < 0.001, by Fisher’s exact test]. The high level of ignorance observed in this study prompted further analyses in order to determine some of the factors responsible. To investigate this therefore, the relationships of awareness scores to such variables as age, year of study, the location of the school (rural or urban), the main source of information about genital defects, and the presence or absence of genital anomaly in the individual were examined. General awareness scores were found to be significantly higher, the higher the age [p = 0.003, by Kruskal-Wallis ANOVA] and the higher the year of study [p = 0.016, by Wilcoxon’s rank sum test]. A classification of the participants according to their major sources of information is as follows: school teacher 312 (51.1%), Mother 1245 (20.0%), both parents 183 (19.0%), Peers 3363 (54.01%), Father 436 (7.0%), and Others 125 (2.01%). Fig 2 shows how the awareness scores were distributed, against the different sources of information. Curiously, there is a statistically significant association between the participants' awareness score and their major source of information about genital anomalies, in descending order of magnitude, as follows; School Teacher, mother, both parents, peers, father, and others, [p = 0.0012, by Kruskal-Wallis ANOVA]. In addition, the median score for general awareness was more among participants with general defects than among their counterparts without such defects, [416 (53.51%) vs. 581 (40.77%) respectively; p = 0.011, by Wilcoxon’s rank sum test]. Taking into consideration the finding in the current study that awareness was associated to both the age and year of study of the participants, [r = 0.29; p = 0.005, Spearman’s correlation], it becomes necessary to explore further, how awareness scores would relate to year of study after controlling for the effect of age. This was achieved by performing regressions of awareness against year of study in each of the following five arbitrarily chosen age brackets, 10.5 - 12.4, 12.5 - 14.4, 14.5 - 16.4, 16.5 - 18.4, 18.5 - 20.4 years. Independently of age, year of study did not significantly correlate with awareness scores [0.003= r = 0.107; 0.062 = p = 0.191, Spearman’s correlations].

Superstitious beliefs abound concerning genital examination that often hampers community survey. Enugu State is one of the Igbo-speaking states of Nigerian South-East. In traditional Igbo Culture, sexuality is a taboo topic. Studies about congenital defects are difficult among people with severe cultural or religious inhibition about sexuality. This is even more difficult in a country such as Nigeria where traditional birth attendants with no iota of knowledge about congenital defects deliver more pregnant women than trained obstetricians. In order to get round these difficulties the current study was designed with a focus on schools. This novel approach, if confirmed reliable, would have the advantage of providing a cheap and quick estimate of the prevalence of genital and other systems' anomalies in a population. The frequencies of the various types of anomalies observed in the study are within the ranges reported in the literature for developed countries. Although there is paucity of reliable local incidence data available for comparison, these preliminary findings appear DISCUSSION deliveries occur outside hospitals. Besides, some anomalies of the external genitalia are congenital and caused during fetal development. Reports from developed countries show that the most common abnormality is failure of the urethral tube to form correctly resulting in an additional hole in the penis. This additional hole is usually located on the underside (hypospadias) or on the topside (epispadias) of the penis. Most of the available epidemiological data available about the prevalence of genital defects are hospital based. However, such incidence data are unreliable in countries such as Nigeria were most encouraging enough for further studies to be undertaken aimed at a within-population validation of the novel sampling. In the current study however, the most frequently observed anomaly was testicular maldescent in 4.30% of the subjects, although the observed frequencies of hypospadias and epispadias were within reported ranges. It is not known, whether the predominance of maldescent found in this study is a reflection of reality or is it merely an artifact of this sampling method. The frequency of genital anomalies found was higher in rural than in urban schools. Although certain environmental factors have been found to play a role in some places, it is not possible to draw a conclusion in this case. Further studies are certainly necessary to explain this rural-urban discrepancy. Awareness was also observed to be lower, despite the observed higher frequency of genital defects in rural schools.

Nigerian Journal of Clinical Practice June 2007, Vol.10(2) Patterns of external Male Genital. O.F Ozoemen. et.al
The later may partly be attributable to the overall high illiteracy level and superstitious beliefs that typify the rural areas in Igbo land. The major anomalies of the genito-urinary tract may result in disturbances of sexual and reproductive functions. In general the children grow up with the same aspirations as their more normal peers, which are to marry, have intercourse and produce children. Some achieve this despite the deformities, and in others specific reconstructive surgery may be needed. Parental awareness is of paramount importance for the early detection and intervention in such cases. The overall awareness about developmental anomalies of the male external genitalia was found to be low among the students in this study. This possibly reflects an over-all low awareness in the society. This hypothesis is further strengthened by the observation that as high as 44% of the affected students were completely unaware that they had such defects. An incidental finding was that only 312 constituted about 5% of the students, gained apparently high quality knowledge about congenital genital anomalies from their teachers, resulting in high scores on the awareness scale. (Median = 56.93%). On the contrary, a majority of the students, (5914) or 95% appear to have gained low quality knowledge from the other sources to which they were exposed, (mother, father, both parents, peers and others), and this probably resulted in their poor scores on the same scale, (median = 38.69%). Although a highly effective source of information, the contribution of formal sex education to the overall awareness about genital defects among the students appears, therefore negligible. The additional finding that awareness scores independently increased with age but not with the year of study further corroborates this tentative interpretation.

CONCLUSION
The burden of anomalies of the external male genitalia among Igbo Nigerians appears to be higher than generally appreciated because of the low level of awareness. It is recommended; therefore that formal sex education is made compulsory in schools as an important first steps towards arresting the situation.

ACKNOWLEDGEMENT
We gratefully acknowledge the assistance of Prof. F.N. Udoh of Urology unit, Department of Surgery, U.N.T.H.Enugu.

We also thank the management of the University of Nigeria Teaching hospital, and all the secondary schools that participated in the study. Special thanks to Lady L.U. Ozoemena who linked us to the various schools and parents of the students where necessary. Finally we want to thank in a special way the SODINAK group of company Ltd for sponsoring this project.
