**Introduction**

Elevated skull fractures, previously thought of as a very rare variety of fractures, are no longer very uncommon. They are expectedly gradually finding a slowly growing list of references in neurosurgical literature. They are mostly posttraumatic compound fractures due to the mechanism of injury. Outcome of operative neurosurgical care is generally rewarding.

**Materials and Methods**

A 4-year retrospective study of case notes, operation registers, and radiology records of patients diagnosed with elevated skull fractures who had neurosurgical care at the University of Nigeria Teaching Hospital, Enugu, Nigeria, between 2012 and 2015, was done. Only patients with evidence of elevated skull fracture on head computed tomography scan were included. The presenting Glasgow Coma Score and Extended Glasgow Outcome Score (GOSE) at the time of discharge from the hospital and 6 months thereafter were analyzed.

**Results**

Out of 209 patients managed with skull fractures over the study period, eight met the inclusion criteria. Seven (87.5%) were males. The latency to presentation was 6 h in one case and >8 h in the other cases. All the patients had operative care involving debridement, duroplasty, and bone-fragment realignment (cranioplasty) either primarily or on an interval basis. The GOSE at 6 months was at least 7 in 87.5% of the patients.

**Conclusions**

Despite the grotesque appearance at presentation, outcome of properly managed elevated skull fractures is good.

**Keywords:** Cranioplasty, duroplasty, elevated skull fracture, extended Glasgow Outcome Score

Onyia, et al.: Elevated skull fractures

and computed tomography (CT) scan evidence of elevated skull fractures were included in the study. Their demographic, clinical, and radiologic data were analyzed. The management of the patients involved the perioperative administration of broad-spectrum antibiotics – intravenous ceftriaxone and metronidazole; wound debridement; removal of loose bone fragments; dural repair (duroplasty); and bone fragment realignment. Dural repair was achieved by simple closure, use of autogenous temporalis fascia, or pericranial graft. Bone fragment realignment (autogenous cranioplasty) was done either primarily or in a delayed fashion. The trauma-presentation and trauma-surgery intervals were estimated. The presenting Glasgow Coma Scale Score was noted.

The outcome measures were extended Glasgow Outcome Score (GOSE) at the time of discharge from the hospital and 6 months thereafter. The available literature on elevated skull fractures was reviewed from a search of PubMed and African Index Medicus and compared with data from these patients.

RESULTS

Out of 209 patients managed with skull fractures over the study period, 8 had elevated skull fractures. Seven of them (87.5%) were male and one (12.5%) was female. Only one of the patients was within the pediatric age group – a 13-year-old boy. The other 7 were all adults, with ages ranging from 18 to 47 years.

Various modes of injury were implicated in the etiology of the fractures [Table 1], the most common of which was assault to the head with a machete (three cases). All the eight patients suffered compound elevated fractures with mild or moderate head injuries (presenting Glasgow Coma Scale [GCS]: 9–15).

The management of the patients involved the perioperative administration of broad-spectrum antibiotics – intravenous ceftriaxone and metronidazole; wound debridement; removal of loose bone fragments; dural repair; and bone fragment realignment. Dural repair was achieved by simple closure in two cases, autogenous temporalis fascia graft in one and autogenous pericranial graft in the other five. Bone fragment realignment was done primarily in four of the eight patients. However, due to extensive wound contamination and delayed presentation in the other four patients, the elevated bone fragment was thoroughly saline-washed and placed in a subcutaneous abdominal pouch for interval autogenous cranioplasty. The trauma-surgery interval in this series ranged from 19 h to 9 days, largely due to delayed presentation.

We had very good outcome in seven patients [GOSEs in Table 1]. The only mortality was from the patient with gunshot head injury and this occurred following an intracranial suppurative process.

Onyia, et al.: Elevated skull fractures

Discussion

An elevated skull fracture is one in which the fractured bone fragment is lifted above the level of the surrounding intact skull.\textsuperscript{[1,6,8,13]} Though recognized as early as in the historical surgical manuscript, the Edwin Smith Papyrus, it is a rarely reported pattern of skull fracture.\textsuperscript{[8]}

Its mechanism of occurrence is the tangential application of force to the scalp, skull, brain, and its meninges.\textsuperscript{[1]} This commonly results from assault with sharp-edged weapons such as machetes, as was suffered by three of the patients in this study.\textsuperscript{[8]} Factors that may contribute to elevation of the fractured bone fragment by this mechanism include lateral pull of the weapon of injury during retrieval and rotation of the head during impact.\textsuperscript{[1,14]} An interesting observation here was that the resulting elevated bone fragments were floating, with minimal underlying brain injury. With the recent upsurge of attacks by community invaders in the south-east and other regions of Nigeria, the incidence of elevated skull fractures may actually be on the rise and may be underreported.

Other modes of injury associated with elevated skull fractures include domestic violence, road accidents, fall from height, animal attack, crane accident, railway accident, gunshot, and blast injury.\textsuperscript{[8,11,15‑18]} They are less common causes of elevated skull fracture. Unsurprisingly, therefore, motorcycle and motor vehicular accidents, though common modes of head injury in this environment, were responsible for only one caseapiece, in this series. Elevated skull fracture from gunshot as in case 4 has also been reported in literature.\textsuperscript{[15]} The mode of injury noted in case 1 (a falling tree branch striking the head, leading to a fall from a 6-m height) is, however, not previously reported in the etiology of elevated skull fracture, to the best of our knowledge.

Majority of published cases of elevated skull fractures were in adults. They are rarely reported in children.\textsuperscript{[11]} The finding of only one pediatric patient in this series therefore comes as no surprise.

In this study, all the eight patients suffered compound elevated fractures, consistent with findings in most reports that elevated skull fractures are also compound and may occasionally simulate a formal craniotomy.\textsuperscript{[10,11,19]} They may occur either in isolation as in six of the cases, or in combination with a depressed fracture – “mixed elevated-depressed,” as in cases 4 and 6.\textsuperscript{[10,11,19]} It is worthy of note, however,
that “simple” elevated skull fracture may rarely occur, as reported by Chhiber et al. and Kumar et al. in their separate reports.\textsuperscript{[11,14]} We did not encounter such case in this study.

Clinical features of elevated skull fractures depend on the site and extent and severity of associated brain injury.\textsuperscript{[1,10,11,13]} The variation in GCS scores found in the patients in this study is a reflection of various degrees of associated brain trauma – in keeping with the variations in presenting GCS seen in literature. In Bokar’s series of three patients, one had a GCS of 15 on presentation, while another was brought in dead.\textsuperscript{[10]} In Kumar’s series of five patients, three had severe head injury, while the remaining two had moderate and mild injuries, respectively. The severity of injury and the resultant neurological manifestations in elevated skull fracture vary. They depend on the degree of injury to the underlying brain parenchyma and may range from minor ones to fatal ones.\textsuperscript{[8,10,13]} In general, however, the injury to brain and associated structures is considered less severe in elevated fractures, due to the characteristic tangential impact, compared to depressed fractures which result from a perpendicular impact, with a more direct vector of force transmission to the brain.\textsuperscript{[8]} For the same reason, the degree of scalp and bone injury in elevated fractures may be relatively large compared to that of the underlying brain, as much of the incident force is dissipated tangential to and away from the cortical surface,\textsuperscript{[1,16]} this may account for the relatively good presenting GCSs seen in our series.

Common underlying injuries include dural laceration, brain contusion, and epidural hematoma.\textsuperscript{[3,14]} Most cases of elevated skull fracture are associated with dural breach, as seen in all the eight patients in this study, but a few cases of intact dura have been reported.\textsuperscript{[12-14,16]} Though we did not find an associated epidural hematoma in any of our patients, we consider the possibility that in some of the cases, the elevated bone fragment may have allowed egress of the associated hematoma before presentation.

Noncontrast cranial computed tomography is the investigation of choice for elevated skull fracture because it reveals bony abnormality as well as any underlying hematoma and brain parenchymal injury.\textsuperscript{[5,9,10,12,14,16,18]} In cases of suspected superior sagittal sinus occlusion, CT angiography is indicated.\textsuperscript{[20]} All patients in this study had cranial CT scan. Angiography was not indicated in any of them.

Elevated skull fractures are usually managed in line with the basic principles of compound skull fracture management such as early recognition and prompt intervention with broad-spectrum antibiotics, wound debridement, removal of loose bone fragments, and dural repair.\textsuperscript{[1,5-13]} Dural repair may be achieved by simple closure when feasible, or by grafting using pericranium, temporalis fascia, or fascia lata.\textsuperscript{[10,11]} In this study, these principles were followed and dural repair was achieved by simple closure in two cases: autogenous temporalis fascia graft in one and autogenous pericranial graft in the other five. On the rare occasion, repair of dural rent has been avoided due to the close proximity of the rent to the superior sagittal sinus as was reported by Abu Talha et al. Instead, the dural tear was closed with gelfoam.\textsuperscript{[20]}

The elevated bone flap at the fracture site has been handled in various ways in previous reports. These include replacement after thorough cleaning and washing, storage away for future cranioplasty due to massive brain swelling, or discarding the bone altogether due to gross wound contamination.\textsuperscript{[13,14,16]} This wide range of options suggests that the decision on handling the bone flap should be individualized. The washing and replacement of the elevated bone flap in a subcutaneous abdominal pouch for future autologous cranioplasty is an option worth considering in patients with significant wound contamination and delayed presentation, especially in resource-challenged environments like ours where functional bone bank facilities are not available.

The outcome of elevated skull fractures generally depends on the amount of contamination, presence or absence of dural breach, underlying brain injury, appropriate and timely antibiotic and antiepileptic medication, trauma-surgery interval, and quality of wound debridement.\textsuperscript{[14,16]} Early surgery is indicated to avoid complications such as meningitis, brain abscess, cerebrospinal fluid fistula, or even death.\textsuperscript{[8,18,20]} The apparent delays in surgical intervention were largely due to delayed presentation to our unit. A focused study and intervention on the reasons for this delay may help ensure earlier presentations, and by extension, shorten the trauma-surgery intervals.

With proper management, elevated skull fractures carry a better prognosis than depressed fractures.\textsuperscript{[8,11,13,16,18,20]} Only few mortalities have been reported in literature, and delayed surgical intervention is a contributing factor.\textsuperscript{[8]} It was instructive that, despite the grotesque appearance of these patients at presentation, the odds favored survival See Figure 3c.

**CONCLUSIONS**

Elevated skull fractures are increasingly gaining recognition in literature, and may be more common than previously thought. The injury mechanism is usually striking. Outcome is generally good and rewarding.
Declaration of patient consent
The authors certify that they have obtained all appropriate patient consent forms. In the form the patient(s) has/have given his/her/their consent for his/her/their images and other clinical information to be reported in the journal. The patients understand that their names and initials will not be published and due efforts will be made to conceal their identity, but anonymity cannot be guaranteed.
