ABSTRACT

Introduction: The hydatid disease most often involves the liver and the lungs. The disease can involve any part of the body except the hair, teeth and nails. Primary extrahepatic-pulmonary hydatid cysts are rare and only a few sporadic cases have been reported. Materials and Methods: Two hundred and forty-four patients with hydatid cysts managed surgically from January 2005 to December 2009 were evaluated retrospectively. Fourteen (5.7%) patients had isolated involvement of the atypical sites, while six (2.4%) also had a primary involvement of liver. Results: The cysts were present in gall bladder (0.4%), peritoneum (1.6%), spleen (1.6%), ovary (0.4%), subcutaneous (0.8%), seminal vesicle (0.4%), spinal (0.4%), pancreas (0.4%), kidney (0.4%), mediastinal (0.4%), muscle (0.4%), and brain (0.8%). Discussion and Conclusions: Involvement of sites other than liver and lungs by hydatid disease is rare. Symptoms are related to size, location or possible complication of the cyst. It should be strongly suspected in differential diagnosis of all abdominal cysts especially in an endemic area. Proper surgical and medical management to avoid any recurrences, and a regular follow-up, are of utmost importance to detect any late complications such as local recurrence of the disease and development of hydatidosis at the primary sites.

KEYWORDS: Atypical locations, hydatid, echinococcosis

INTRODUCTION

Echinococcal disease in humans is a parasitic tapeworm infection caused by a larval stage (the metacestode) of Echinococcus species (Echinococcus granulosus, Echinococcus multilocularis, Echinococcus oligarthrus, or Echinococcus vogelii). The infection can be asymptomatic or severe, causing extensive organ damage and even the death of the patient.31

Hydatid cyst has a worldwide distribution and has been recognized since ancient times. Human hydatidosis is a parasitic infection of the liver and other organs caused by the flatworm Echinococcus, most commonly Echinococcus granulosus which is a 5 mm long hermaphroditic tapeworm that has dog, foxes or coyotes as the definitive host and sheep, swine, cattle, and zebra as the intermediate host. Man is an accidental, intermediate host, and infection of humans represents a terminal event (dead end) for the parasite. Once within the man or other intermediate host the ingested eggs hatch in the duodenum to release the true larvae (oncospheres) that penetrate the mucosa of small intestine and enter the portal circulation. Liver acts as the first effective filter for most of the larvae and therefore being the most common site of involvement (65–75%). If the larvae pass through the first filter, they reach the lungs which are the second most frequently involved site (10–25%). If the larvae are not trapped in either liver or lungs, or if they by-pass the liver by traveling via lymphatics, it may lodge itself in any part of the body including the peritoneal cavity (8–18%), spleen (2–3%), kidneys (1–4%), uterus and adnexa (0.5–1%), retroperitoneum (0.5–1%), pancreas (0.5–0.8%), subcutaneous (1–2%), mediastinum (0.1–0.5%), gall bladder (≤1%), brain (2%), seminal vesicle, spinal and others (0.1-3%).31 We present our experience with atypical sites of hydatidosis, including the diagnostic evaluation and surgical treatment.

MATERIALS AND METHODS

Two hundred and forty-four patients with hydatid cysts managed surgically from January 2005 to December 2009 at S.K.I.M.S., Soura, Srinagar, Jammu and Kashmir, India, were evaluated retrospectively. Of these patients 142 (58.1%) were males and 102 (41.8%) females. Patient age ranged from 16 to 76 years. Liver was involved in 187 patients, of which 161 (65.9%) had had isolated liver disease, 20 (8.1%) had associated lung cysts,
and another 6 (2.4%) patients had concomitant echinococcosis at atypical locations. Isolated lung involvement was seen in 43 (17.6%) patients. Fourteen patients (5.7%) had primary isolated hydatid cysts involving atypical locations. Only those patients with hydatid disease at atypical locations (n=20) were included in the study, including the six patients with concomitant disease of the liver. The atypical locations of the disease included the gall bladder, peritoneum, spleen, ovary, subcutaneous, seminal vesicle, spinal, pancreas, right kidney, mediastinal, muscle, and the brain [Table 1].

Preoperative diagnosis was established by the history, clinical examination, complete blood counts, liver and kidney function tests, serological tests (enzyme linked immunosorbent assay and indirect hemagglutination test), X-ray chest, ultrasound and magnetic resonance imaging (MRI) or contrast enhanced computerized tomography (CECT). The treatment for all the patients was surgical. All the patients received preoperative and postoperative albendazole chemotherapy.

Nonspecific abdominal pain and a nontender palpable abdominal lump were the most predominant symptoms; other symptoms varied according to the localization of the cyst. Palpable lump was also a presenting symptom in patients with subcutaneous and muscle cysts. Four patients with atypical locations were asymptomatic, which included two cases with peritoneal hydatid, one case each of isolated splenic and renal hydatid. Patients with brain and spinal hydatid presented with neurological symptoms, while the one with seminal vesicle hydatid presented with lower urinary tract symptoms (LUTS). Acute popliteal artery embolism due to a laminated membrane was the presentation in the patient with a primary mediastinal hydatid cyst, which had ruptured into descending thoracic aorta [Table 1].

Eosinophilia was observed in 14 of 20 patients. Diagnosis was confirmed by hydatid serology, ultrasonography, MRI/CECT [Figures 1-8], and histopathological examination of the specimen. These investigations were applied to all the patients.

### Results

Hydatid disease involving atypical sites was seen in a total of 20 (8.1%) patients. Among this study group, primary isolated hydatid cysts involving atypical locations were present in 14 (5.7%) patients. These included solitary cases of seminal vesicle (0.4%), spinal (0.4%), pancreatic (0.4%), renal (0.4%), mediastinal (0.4%), and muscular (0.4%) hydatid cysts, while involvement of subcutaneous tissue and brain was seen in two each (0.8% each) of the patients. Three patients (1.2%) had isolated involvement of the spleen. Six (2.4%) patients also had a primary disease in the liver. Atypical locations involved in these included peritoneum in 3 (1.2%) and gall bladder (0.4%), spleen (0.4%), and ovary (0.4%) in each [Table 1].

Surgical treatments include complete cyst excision (cystopericystectomy) in most of the patients. Nephrectomy, cholecystectomy, ovarian cystectomy, distal pancreatectomy and splenectomy, were performed whenever cysts invaded these organs. Classic manoeuvre by Dowling and Orlando was used in management of cerebral hydatid cyst. Epidural hydatid with paravertebral extension was dealt by D 10/11 lamnectomy and complete cyst excision. All the patients were given postoperative chemotherapy (Albendazole 10 mg/kg/day) for three cycles of 21 days each with a gap of 1 week between each cycle. The postoperative hospital stay ranged between 2 and 14 days. Morbidity was minimal, with a wound infection recorded postoperatively in one case treated with splenectomy. The

Mushtaque, et al.: Atypical localizations of hydatid disease

Figure 1: CECT abdomen: Documented hydatid cyst in right lobe of the liver. Another cystic lesion with thick calcified wall was seen in segment-VI of liver measuring 5x5 cm. A calcified area 2 cm in size was also seen medial to the above-calcified cystic lesion. The gall bladder was not seen separately from the calcified cystic lesion. IHBR and CBD were normal

Figure 2: CECT abdomen showing cystic lesion of the spleen involving upper half of the organ

Figure 3: MRI showing multicystic swelling overlying gluteus maximus which is hyperintence on T2WI/STIR and hypointence on T1WI images. Thick septa seen within and surrounding tissue showing edema

Figure 4: Axial T2WI (MRI) showing hyper intense, multicystic lesion with multiple daughter cysts in relation to the right seminal vesicle

Figure 5: Axial T2WI (MRI) showing hyper intense, multicystic lesion with multiple daughter cysts in the para spinal region with extension into epidural space

dIscussIon

Hydatid disease is seen endemically among sheep raising communities. The disease still continues to be a serious problem in countries like Australia, New Zealand, Middle East, Africa, India, South America, Turkey, and Southern Europe. The disease is attributed to occupational exposure during farming practices (sheep rearing), particularly in rural areas; ingestion of contaminated vegetables, drinking of egg-contaminated water (containing hexacanth larvae), and traditional intake of mutton and beef. Because the practice of close contact with domestic animals such as dogs is rare in Kashmir, which is Muslim dominated, the sheep-dog association apparently seems to be most commonly implicated in the life cycle of the parasite. Buffalo-dog, goat-dog, cow-dog, and horse-dog associations are also possible.

Although liver and lungs are the most common sites involved,
Mushtaque, et al.: Atypical localizations of hydatid disease

various atypical sites involved by hydatid cysts and reported in literature include those of peritoneal cavity, spleen, kidneys, uterus and adnexia, retroperitoneum, pancreas, subcutaneous, mediastinum, gall bladder, brain, seminal vesicle, para-spinal, and others.\[2-8,10-19\] In our study, we presented atypical locations of hydatid cysts from a single tertiary care center. Diagnostic and therapeutic strategies are also summarized from the surgical and radiological perspective. Although portal blood stream remains the main pathway of parasite spread, normally existing porto-caval shunts, lymphatic invasion by the parasite, and retrograde migration from vena cava to subclavian vein have been documented and explain some of these rare sites\[1,12\]

Atypical localization of hydatid disease usually poses a diagnostic dilemma. It is well known that specific local or general symptoms and signs of hydatid disease do not exist. The majority of cases are diagnosed following incidental findings at imaging examinations for sometimes unrelated complaints. The uncommon localization frequently causes diagnostic problems and specific diagnostic tests do not have 100% reliability in these cases.\[7\]

Hydatid disease in extrahepatic locations usually follows a silent clinical course unless it grows and produces pressure symptoms or develops complications which may include local pressure, rupture, secondary infection, and an allergic reaction.\[20\] Most of these cases are associated with cysts at the primary location, but in our series all except six patients had isolated primary location of hydatid disease at an atypical site.

In our series, a lump was the presenting feature in cases with hydatid disease involving subcutaneous tissue and thigh muscle. Patient with para spinal disease presented with low back pain, weakness, and paraplegia. Pain abdomen and organomegaly/lump was seen in gall bladder, pancreatic, and splenic hydatid. Seminal vesicle hydatid presented with lower urinary tract

**Figure 6:** CECT abdomen showing a cystic lesion (unilocular) involving pancreas

**Figure 7:** CECT chest documented a primary mediastinal hydatid cyst (cystic laminated structure) eroding into the descending thoracic aorta with contrast leak from aorta into the mediastinal cyst

**Figure 8:** NCCT head showing a multicystic lesion, with multiple daughter cysts in left cerebral hemisphere and compressing the ventricles and opposite lobe
symptoms, while the patient with brain hydatid presented with severe headache, vomiting, drowsiness, and hemiparesis. Acute popliteal artery embolism due to a laminated membrane was the presentation in the patient with a primary mediastinal hydatid cyst, which had ruptured into descending thoracic aorta. Four patients with atypical location of hydatid were asymptomatic. It is important to think of hydatid disease as a possibility in patients with nonspecific symptoms with a cystic lesion at any location, especially in endemic areas like India.

Routine laboratory tests can only reveal eosinophilia. Diagnosis is established by imaging and serological tests. Highly sensitive tests include an indirect hemagglutination test (IHA), and a direct agglutination test (LA). Specific tests include double diffusion test (DD), immunoelectrophoresis (IEP), enzyme linked immunosorbent assay (ELISA), and radioallergosorbant test (RAST). Many authors recommend preoperative use of antihelminthics to sterilize the cyst, and reduce the chances of spillage, anaphylaxis, and dissemination at surgery. Postoperative medical treatment reduces the chances of recurrence. Our patients received albendazole (10 mg/kg/day) for 4 weeks preoperatively.

Surgery still remains the mainstay of treatment for hydatid disease with special attention to avoid any spread of hydatid from other lesions.

Mushtaque, et al.: Atypical localizations of hydatid disease

Medical treatment alone may be effective in 30–40% of cases. It is most effective in alveolar hydatid, less so for liver infection, and essentially ineffective for the diseases of bone, brain, eye, gall bladder and other sites. Many authors recommend preoperative use of antihelminthics to sterilize the cyst, and reduce the chances of spillage, anaphylaxis, and dissemination at surgery. Postoperative medical treatment reduces the chances of recurrence. Our patients received albendazole (10 mg/kg/day) for 4 weeks preoperatively.

Conclusions

Echinococcosis can appear at any site of the human body, and so should always be considered in the differential diagnosis of cystic space-occupying lesions or unidentified tumor formations in patients from endemic areas. Proper surgical and medical management to avoid any recurrences, and a regular follow-up, are of utmost importance to detect any late complications such as local recurrence of the disease and development of hydatidosis at the primary sites.
