ABSTRACT: Developing an efficient rotary oven that is capable of addressing the issue of long baking duration and uneven heating distribution during baking could aid in encouraging indigenous use of the oven by small and medium scale bakeries in developing countries. This study aimed to develop and evaluate the performance of a rotary oven. Taguchi experimental design was used to investigate the influence of oven temperature (160, 180, 200°C) and oven rack speed (0, 10, 20 rpm) on the physical properties (baking time, mass, surface area, specific volume and density) of bread produced from the rotary oven. The baking capacity and efficiency of the rotary oven were 16 kg h⁻¹ and 94%, respectively. Investigation showed that baking time ranges from 20 to 82 min, bread mass (884 to 925.7 g), surface area (1050 to 1370 cm²), specific volume (2.36 to 3.70 cm³ g⁻¹) and density (0.25 to 0.39 g cm⁻³), respectively. The optimum baking time (20 min) was achieved at 200°C oven temperature and 10 rpm oven rack speed. The oven could be adopted for both domestic and industrial production of bread and other bakery products.

KEYWORDS: Bread, oven temperature, oven rack speed, taguchi, rotary oven.

[Received November 15, 2019, Revised May 22, 2020, Accepted August 24, 2020]  Print ISSN: 0189-9546 | Online ISSN: 2437-2110

I. INTRODUCTION

Oven is one of the key food processing equipment that uses complex simultaneous heat and mass transfer process in the food industries. It is a thermally insulated chamber used for heating, baking, cooking, or drying of food substances (Monda and Datta, 2009; Adegbola et al., 2012). Baking is a widely used processing technique that plays an important role in determining the quality of the final product. Bread, cakes, biscuits, brownies, casseroles, cookies, pastries, puddings and tarts are examples of baked products. For efficient baking, there must be minimal moisture loss. According to Morakinyo et al. (2017), during baking, the driving force of heat transfer is the temperature gradient while that of mass diffusion is concentration difference. The heat and mass transfer occur simultaneously within the baked food material from the outer part to the inner part of the food material. The moisture diffusion while baking the food material occurs mainly by convection and conduction, less by radiation (Basil and Blessant, 2014). The quality of baked products is usually affected by the time and temperature of the baking process (Mondal and Datta, 2008). During baking, different changes such as volume expansion and crust formation occur in the dough depending on time and temperature (Therdthai et al., 2002).

The development of rotary oven has received considerable attention over the last decade, due to its durability, flexibility and efficiency. Unfortunately, in developing countries, the largescale bakers utilize the imported rotary ovens, which are unaffordable to small-scale or household bakers. Also, most of the existing baking oven used by small-scale bakers takes much time causing long waiting time for the users to have their product ready. Also, their efficiency is usually low with uneven distribution of heat which causes non-uniformity in baking, heat loss through the frequent opening of the oven door while monitoring the baking process and absence of an alarm system that indicates the end of the baking process. Several researchers have attempted to design different types of ovens; Adegbola et al. (2012), designed, constructed and evaluated the performance of low-cost electric baking oven; Ganitha et al. (2014), designed, fabricated and evaluated the performance of domestic gas oven; Okafor (2014) designed a dual powered domestic oven; Morakinyo et al. (2017), developed gas-fired tube oven while Chukwuneke et al. (2018) designed and fabricated dual-powered electric oven. Despite this tremendous effort made by several researchers, there is still paucity of information on the design of rotary oven. Little attention had been paid towards incorporating rotating rack inside an oven. Most researchers used stationary rack in their oven design to address non-homogenous heat distribution and longer baking time issues that were reported by Aborisade and Adewuyi (2014) and Morakinyo et al. (2017) as the shortcomings of the indigenous baking oven.

Taguchi Orthogonal Array (TOA) is a mathematical and statistical technique that is useful for evaluating, improving, and optimizing processes (Sanusi et al., 2020). It is widely used to examine the interactions among process parameters. Many researchers have used this method to optimize factors in food processing (Barna et al., 1997; Mecit et al., 2007; Chao-Chin Chung et al., 2008; Ho-Hsien Chen et al., 2011; Chandrasekar et al., 2015; Sanusi et al., 2020). However, literature is sparse on development of a prototype of an electric

doi: http://dx.doi.org/10.4314/njtd.v17i4.1

*Corresponding author: sanusi.ms@unilorin.edu.ng
rotary oven which can be used in developing countries. Also, only few studies have focused on studying the effect of oven temperature and oven rack speed on some physical properties of bread produced from the rotary oven. Therefore, this study aimed to develop and evaluate the performance of a rotary oven. The study was further extended by using Taguchi technique to determine the influence of oven temperature and oven rack speed on the physical properties (baking time, bread mass, bread volume, surface area, specific volume and density) of bread baked in the developed rotary oven.

II. MATERIALS AND METHODS

A. Design Consideration

The parameters considered in the design of the rotary oven were selected based on the following factors:

i. Sanitary and hygienic properties of the material: construction material that may come in contact with food must be corrosion resistant, must be inert to the food material under its operating conditions and must be non-toxic. Therefore, AISI 304 stainless steel was used for the inner chamber of the oven while mild steel is used for the outer chamber.

ii. Availability of the material and cost: the availability of AISI 304 stainless steel, mild steel and overall cost were considered through critical value analysis in material selection, design and production which will make it affordable to users.

iii. Strength and durability of the material: factors such as; strength, durability, stability, vibration were considered in the selection of appropriate materials for the various components of the oven.

iv. The convenience of use during production: The user-friendly interface between the operator and the oven were considered, i.e. ease of operation, convenient handling, the safety of the operator and those within the area of operation of the machine.

B. Design Calculations

1.) Rotary oven and chamber wall: The dimensions that were used for the design of the rotary oven are shown in the orthographical view in Figure 1.

2.) Volume of oven baking chamber

The baking oven chamber is the enclosed chamber where the baking takes place and the volume was calculated using Eq. (1) as described by Clements et al. (2001).

\[ V = BCL \times BCW \times BCH \]  \hspace{1cm} (1)

where \( V \) is the volume of the baking chamber (mm\(^3\)), \( BCL \) is the baking chamber length, \( BCW \) is the baking chamber width and \( BCH \) is the baking chamber height.

Therefore, the volume of the baking chamber (\( V \)) is equivalent to 0.285 m\(^3\), given the values of 560 mm, 520 mm and 980 mm for \( BCL, BCW \) and \( BCH \) respectively.

3.) Capacity of the oven

The capacity of the oven is the number of loaves of bread that can be baked in the oven per batch. The capacity of the oven was determined using Eq. (2) as described by Okafor (2004). Assuming only 1 oven rack tray:

- The average mass of bread dough = 0.950 kg
- Area of the rack tray = 300 mm (length) \( \times \) 250 mm (width) = 75,000 mm\(^2\).
- Area of loaf of bread considered = 150 mm (length) \( \times \) 150 mm (width) = 22,500 mm\(^2\).

\[ CO = \frac{SRT}{SB} \]  \hspace{1cm} (2)

where \( CO \) is capacity of oven, \( SRT \) is size of rack tray and \( SB \) is size of bread.

Therefore, \( CO \) is equivalent to 3 loaves of bread per rack tray. The oven has three (3) compartments for rack trays which is equivalent to 9 loaves of bread per batch.

4.) Electric energy requirement

The heat required was calculated using Eq. (3) (Anyakoha, 2013).

\[ Q_H = M_b \times C_b \times T_d \]  \hspace{1cm} (3)

where \( M_b \) is mass of bread, \( C_b \) is specific heat capacity of bread and \( T_d \) is difference in temperature.

The average oven baking temperature was 200 °C ≡ 473.15 K; mass of bread is 0.950 kg; Specific heat capacity of bread is 2890 J kg\(^{-1}\) K\(^{-1}\) according to Zheleva and Kambourova, (2005); Oven room temperature is 27 °C ≡ 300.15 K. Therefore, the quantity of heat required to bake 9 loaves of bread per batch, \( Q_H \) is calculated as 4,274,743.5 Joules.

5.) Airflow required

The airflow rate (AF) was calculated using Eq. (4) (Falke, 2016). An air change of 5 m\(^3\)min\(^{-1}\) was assumed since the value was within the recommended for baking oven design.

\[ AF = U \times V \]  \hspace{1cm} (4)

where \( U \) is air changed (m\(^3\)min\(^{-1}\)) and \( V \) is volume of the oven.

In other words, given the values of 0.285 m\(^3\) and 5 m\(^3\)min\(^{-1}\) for \( V \) and \( U \) respectively, the airflow rate (AF) is 1.425 cfm.

6.) The fan design

The fan served the purpose of distributing heat by drawing ambient air from the collector to the heater housing and discharging heated air to the oven chamber. The fan horse power (FHP) was calculated using Eq. (5) (Engineering Tool Box, 2010).

\[ FHP = \frac{AF \times PR}{6320 \times FE} \]  \hspace{1cm} (5)
where $PR$ is pressure rise from fan, $FE$ is fan efficiency.

From literature, most industrial fans have efficiency ranging from 70 - 85%. Assuming a fan with an efficiency of 85% and pressure rise from fan of 1136 mmWg (Bureau of Energy Efficiency, 2005). The fan horse power ($FHP$) was calculated to be 0.30 Hp, given the values of 1.425 cfm, 1135 mmWg and 0.85 for $AF$, $PR$ and $FE$ respectively.

Based on the above calculation, an axial flow fan with 0.5 Hp was selected. An axial flow fan was used to ensure proper distribution of air to the oven chamber and for effective heat distribution (Stadler et al., 2012).
7.) Capacity of the electric heating element

Power (PHE) of the electric heating element was calculated using Eq. 6 (Okafor, 2014).

\[ PHE = \frac{E}{t} \]  

(6)

where PHE is the power of the electric heating element, E is the energy and \( t \) is average processing time per dough batch.

Assuming the average processing time per dough batch is 30 min, thus, from Eq. (3) the quantity of heat supplied to the oven chamber is 4,274,743.5 J.

According to Le-bail et al. (2010), 1.2 J/g of energy is needed to gelatinise starch in bread dough, therefore the heat transfer to the dough is equivalent to;

\[ HTD = EGS \times Q_h \]  

(7)

where HTD is heat transfer to the dough and EGS is energy needed to gelatinise the starch in bread dough.

Therefore, the heat transfer to the dough (HTD) was calculated as 5129692.2 Joules, given the values of 1.2 J/g and 4274743.5 J for EGS and \( Q_h \) respectively. This means that the heating element would supply a minimum of 5129692.2 Joules of heat energy to the oven chamber in 30 min.

Thus, \( PHE = 2849.83 \) J/sec. = 2849.83 W = 2.85 kW

Thus, power of electrical heating element of 3,000 W or 3 kW was selected.

In order to determine the resistance of the heating element and the current required to operate the oven, Eq. 8 and Eq. 9 were used according to Anyakoha (2013).

\[ PHE = \frac{V^2}{R} \]  

(8)

where \( R \) is the electrical resistance (\( \Omega \)), \( V \) is voltage supply in Nigeria.

Thus from Eq. (8), the resistance of the heating element, \( R \), is 20.2 \( \Omega \), given the values of 240 V and 2,849.83 W for \( V \) and PHE respectively.

The current required was calculated using Eq. (9).

\[ I = \frac{PHE}{V} \]  

(9)

The current required for the oven was determined to be 11.87 A, given the values of 2849.83 W and 240 V for PHE and \( V \) respectively.

8.) Selection of Electric Motor

The selection of the motor was based on two parameters viz:

i. Rotational speed

ii. Power consumption

The oven assumes the use of a 3 amps 3 phase electric motor. McCable et al. (1985) approach was used to determine rotational speed as shown in Eq. (10).

\[ mgh = \frac{1}{2}mv^2 \]  

(10)

where, \( m \) is mass of load on the rotor (g), \( g \) is acceleration due to gravity (9.8 ms\(^{-2}\)), \( h \) is height of load from the rotor (0.1 m) \( v \) is speed of the rotor (ms\(^{-1}\)).

From Eq. (10), \( v = \sqrt{2gh} \).

Therefore, the speed of the motor was calculated as 1.4 ms\(^{-1}\), given the values of 9.8 ms\(^{-2}\) and 0.1 for \( g \) and \( h \) respectively.

For motor power (\( P_m \)) consumption determination, Kirsch et al. (1985) was used using Eq. (11).

\[ P_m = VI\sqrt{3} \]  

(11)

The motor power consumption was calculated as 4928.42 W which is equivalent to 4.928 kW, given the values of 240 V, 11.87 A for \( V \) and \( I \) respectively. Therefore a motor with power consumption of 7 Hp was selected.

C. Performance Evaluation of the Rotary Oven

Performance evaluation was carried out to determine the functionality and performance characteristics of the rotary oven. The performance evaluation characteristics were carried out to establish the optimum baking capacity and baking efficiency.

1.) Baking capacity

Morakinyo et al. (2017) approach was used to determine the baking capacity using Eq. 12. The baking capacity of the rotary oven was determined by putting into consideration the three (3) space in the rack compartment (300 mm × 250 mm × 250 mm) and the baking pan for bread dough (150 mm × 150 mm × 150 mm). Nine (9) pieces of bread dough (950 g) each in the baking pan, occupied the rack compartment of the rotary oven and the optimum baking time was determined.

\[ BC = \frac{MD}{BT} \]  

(12)

where, BC is baking capacity, MD is mass of dough (kg) and BT is baking time (h)

2.) Baking efficiency

The baking efficiency of the rotary oven was determined by using the ratio of the designed baking time to the actual baking time required to bake a batch of dough to its desired taste, colour and texture in the rotary oven as calculated in Eq. 13 (Okafor et al., 2014).

\[ BE = \frac{DBT}{ABT} \]  

(13)
where, \( BE \) is baking efficiency, \( DBT \) is designed baking time (min), \( ABT \) is actual baking time (min).

D. Taguchi Experimental Design and Bread Dough Preparation

Taguchi experimental design was used to evaluate the effect of oven temperature and oven rack speed using Minitab 16 statistical software package (U.K). Table 1 shows the Taguchi experimental design \( L_9 (3^2) \). The bread preparation was carried out at the Department of Food Engineering, University of Ilorin, Nigeria. Bread dough was prepared by mixing 57.12% wheat flour, 7.65% sugar, 0.96% vegetable oil, 0.86% salt, 29.02% water, 1.83% milk, 0.69% yeast (Saccharomyces cerevisiae) and 1.87% margarine using a fabricated planetary dough mixer. The bread dough was divided, moulded into 950 g of six (6) pieces each and were placed inside clean and oiled baking pans (150 mm × 150 mm × 150 mm).

The dough was proofed in a fabricated proofer at proofing temperature of 40°C for 45 min. After the proofing process, the proofed dough was transferred and arranged on the oven rack trays inside the rotary oven and allowed to bake at a varying oven temperature of 160°C, 180°C and 200°C and oven rack speed of 0 rpm (stationary), 10 rpm and 20 rpm based on Taguchi orthogonal array experimental designed. Nine (9) treatments at different conditions were obtained from Taguchi design and the bread obtained were analysed for the effect of oven temperature and oven rack speed on the physical properties (baking time, bread mass, bread surface area, specific volume and density).

Table 1: Experimental design using Taguchi \( L_9 (3^2) \).

<table>

</tr>
<tr>
<td>Oven rack speed (rpm)</td>
<td>0 10 20</td>
</tr>
</tbody>
</table>

*0 rpm means at the rack is at a stationary position

2.) Baking time

An instant-read thermometer (Model: DTH-81, Palermo) was used to measure the bread doneness. The thermometer was inserted into the centre of the loaf side at intervals. Digital stopwatch (Model: Fastime 20) was used to monitor the baking time and the baking was terminated at an internal thermometer reading of 210°F or 98°C (Martin, 2018). Baking time was recorded for each treatment.

3.) Bread mass, specific volume and density

The baked bread samples were weighed 1 h after baking using a digital weighing scale (Cammry, Model ACS-ZE21W, China) ± 0.01 g precision scale. At that point, the volume of the bread was measured by rapeseed displacement according to the American Association Cereal Chemists (AACC) method 10-05 (2001). The obtained results were used to determine the specific volume (cm³ g⁻¹) and density (g cm⁻³).

4.) Bread surface area

Bread surface area was calculated using Eq. 14 as described by Morakinyo et al. (2017). Parameters such as length (l), width (b) and height (h) were measured using a digital vernier caliper (Model AD-5765-100, China) having a sensitivity of 0.01 mm.

\[
SA = 2(lb + bh + lh) \tag{14}
\]

where \( SA \) is the surface area

E. Statistical Analysis

All determinations were performed in triplicates (n=3). All data were subjected to one-way analysis of variance (ANOVA) and means were separated using Duncan’s Multiple-Range Test (DMRT) at \( p<0.05 \) using SPSS 20.0 software package (SPSS, Inc., U.K).

III. RESULTS AND DISCUSSION

A. Description and Mode of Operation of the Rotary Oven

A prototype of a rotary oven was developed for baking purpose. The rotary oven is a compact type of oven that uses the three modes of heat transfer (conduction, convection and radiation) to bake food products. Auto Inventor Professional 2017 (U.S) was used for drawing the orthographic, exploded and isometric projections of the rotary oven. Figures 2 and 3 showed the exploded and isometric view of the rotary oven. The exploded view of the rotary oven, which consists of the components parts used for oven. The major materials used for the construction of the rotary oven were: AISI 304 stainless steel for the construction of the interior chamber, mild steel for the construction of the exterior chamber, glass fibre was used for lagging the oven to prevent heat loss from the oven cavity and removable rack to hold food products to be baked.

The oven has a heat resistance glass door to enhance the ease of monitoring of product during the baking process. Heating element and fan are other key components of the oven. The speed of the fan varies automatically with the temperature of the heating element. The pressurized air from the fan is passed through the heating element and at the same time been heated before entering into the oven cavity where the baking takes place. A control panel meant for setting baking time, baking oven temperature and for regulating the speed of rotor that holds the removable rack was also incorporated. The timer was connected to an alarm system that indicates when the appropriate baking time and the temperature are reached. Also within the rotary oven is a thermostat that checks and helps regulate the temperature of the oven. The thermostat ensures the temperature within the oven does not exceed the set temperature by the operator. Plate 1 shows the picture of the rotary oven.
B. Effect of Oven Temperature and Oven Rack Speed on Baking Time

Baking time is one of the key operational parameters used in evaluating the performance of an oven. Short baking time signifies an efficient oven with high production rate tendency. Figure 4 shows the surface plot of the effect of oven temperature and oven rack speed on baking time. The shortest baking time was 20 min at 200 °C oven temperature and 10 rpm oven rack speed while the longest baking time was 82 min and it occurred at an oven temperature of 160 °C and oven rack speed of 0 rpm. Table 2, shows that baking time varies significantly at p≤0.05. It was observed that as temperature increases, there was a reduction in the baking time. This could be attributed to an increase in temperature profile due to heat transfer, which accelerates baking rate, thus reduces the baking time. The results are in agreement with the findings of Ureta et al. (2016), that no matter the conventional mode of heat transfer, baking time decreases with an increase in oven temperature. Morakinyo et al. (2015) also observed a similar trend. However, an increase in oven rack speed from 0 to 10 rpm reduces baking time while an increase from 10 to 20 rpm resulted into increase in baking time. This might be attributed to the steady rotation of oven rack at 10 rpm, which allows even distribution of hot air than at 20 rpm. Also, the rate of hot air penetration into the bread dough might decrease due to the increase in oven rack speed which could also result in the longer baking time observed at 20 rpm. Eq. 15 shows the quadratic regression model relating the effect of oven temperature and oven rack speed on baking time (BT).

\[ BT = 860.668 - 7.554x_1 - 10.133x_2 + 0.017x_1^2 + 0.047x_2^2 + 0.048x_1x_2 \]  

where, \( x_1 \) and \( x_2 \) are oven temperature and oven rack speed. The coefficient of determination (\( R^2 \)) and \( R^2\text{(adj)} \) obtained for the model was 94.80% and 86.14%. According to Peng et al. (2019), \( R^2 \) value of more than 75% is considered accurate in developing a statistical model. Also, Mazaheri et al. (2017) reported that the closeness between \( R^2 \) and \( R^2\text{(adj)} \) values and the lower the value of \( R^2\text{(adj)} \) compared to the \( R^2 \) value, for the model, indicates the goodness of data fit. Therefore, this model is fit to predict the influence of oven temperature and oven time on baking time.

C. Effect of Oven Temperature and Oven Rack Speed on the Mass of the Baked Bread

Bakers prefer bread with minimal weight loss that is why information on the mass is important. Figure 5 shows the surface plot effect of oven temperature and oven rack speed on the mass of baked bread under different conditions. The highest bread mass (925.67±2.08 g) was observed at 180°C oven temperature and 10 rpm oven rack speed while the least bread mass (884.00±5.00 g) occurred at 160°C oven temperature and 0 rpm oven rack speed. However, there was no much disparity (Table 2) between the bread mass (916.33±3.06 g) at 200°C oven temperature and 10 rpm oven rack speed and the bread mass (925.67±2.08 g) at 180°C oven temperature and 10 rpm oven rack speed. The difference in the bread mass could be as a result of moisture loss and increased baking time. As the baking time increases at lower oven temperature, there is a slow process of crust formation which leads to more moisture loss. Therefore, the rate of crust formation might also be responsible for the differences observed in the bread mass. These results corroborate the previous findings of Bahnasawy and Khater (2014) and Genitha et al. (2014) that as baking time increases, weight loss increase which further leads to mass loss. Eq. 16 shows the quadratic regression model relating the effect of oven temperature and oven rack speed on bread mass.

\[
Bread\ mass = -616.463 + 15.997x_1 + 10.772x_2 - 0.041x_1^2 + 0.041x_2^2 - 0.063x_1x_2
\]  

(16)

where, \(x_1\) and \(x_2\) are oven temperature and oven rack speed. The coefficient of determination \((R^2)\) and \(R^2_{(adj)}\) obtained for the model was 90.79\% and 75.44\%. Therefore, this model is capable of predicting the influence of oven temperature and oven rack speed on bread mass.

D. Effect of Oven Temperature and Oven Rack Speed on the Bread Surface Area

Figure 6 shows the surface plot effect of oven temperature and oven rack speed on the surface area of the bread. It was observed that the minimum bread surface area (1050.00 cm\(^2\)) was recorded at 160°C oven temperature and 20 rpm oven rack speed, while the maximum bread surface area (1370.00±34.64 cm\(^2\)) was achieved at an oven temperature of 160°C and oven rack speed of 10 rpm.

![Figure 6: Surface plot of the effect of oven temperature and oven rack speed on bread surface area](image)

However, there was no significant different \((p<0.05)\) between the bread surface area (1340.00±17.32 cm\(^2\)) observed at 200°C oven temperature and 0 rpm oven rack speed and that of 160°C oven temperature and 10 rpm oven rack speed. The oven spring and the rack rotation that occurred at the temperature might be responsible for the maximum surface area observed at the temperatures. Table 2 shows a significant difference in the baked bread surface area at different conditions. However, these results slightly agree with Morakinyo et al. (2017) findings which stated that maximum bread surface area was observed at 180°C rather than at 200°C while studying the performance of the developed gas-fired baking oven. Eq. 17 shows the quadratic regression model relating the effect of oven temperature and oven rack speed on the bread surface area.

\[
Bread\ surface\ area = 7691.50 - 75.52x_1 + 29.58x_2 + 0.22x_1^2 + 0.84x_2^2 - 0.09x_1x_2
\]  

(17)

where, \(x_1\) and \(x_2\) are oven temperature and oven rack speed. The coefficient of determination \((R^2)\) and \(R^2_{(adj)}\) obtained for the model was 52.56\% and 0.00\%. Therefore, this model is not fit to predict the effect of oven temperature and oven rack speed on the bread surface area. This could also imply that more factors aside oven temperature and oven rack speed could influence bread surface area.
E. Effect of Oven Temperature and Oven Rack Speed on the Bread Specific Volume

Bread specific volume is one of the major quality-determining criteria for bread quality. Bread with a larger volume is always preferred. Figure 7 shows the surface plot of the effect of oven temperature and oven rack speed on the specific volume of baked bread. The least bread specific volume (2.36±0.00 cm$^3$ g$^{-1}$) was recorded at an oven temperature of 160 °C and oven rack speed of 20 rpm, while the highest specific volume (3.70±0.13 cm$^3$ g$^{-1}$) was recorded at an oven temperature of 160 °C and oven rack speed of 10 rpm.

The result showed that there was no significant difference (p≤0.05) in the bread specific volume at 160 °C oven temperature and 10 rpm oven rack speed, and at 200 °C oven temperature and 0 rpm oven rack speed (3.51±0.08 cm$^3$ g$^{-1}$). Eq. 18 shows the quadratic regression model relating the effect of oven temperature and oven rack speed on bread specific volume.

$$\text{Bread specific volume} = 28.35 - 0.292x_1 + 0.087x_2 + 0.0008x_1^2 - 0.0034x_2^2 - 0.0002x_1x_2$$ (18)

where, $x_1$ and $x_2$ are oven temperature and oven rack speed. The coefficient of determination ($R^2$) and $R^2_{(adj)}$ obtained for the model was 49.13% and 0.00%. This model is not fit to predict the effect of oven temperature and oven rack speed on bread specific volume. This could imply that more factors aside oven temperature and oven rack speed might influence the bread specific volume.

F. Effect of Oven Temperature and Oven Rack Speed on the Bread Density

The effect of oven temperature and oven rack speed can be related to the density of the baked bread as shown in the surface plot in Figure 8. It was observed that the maximum density (0.39 g cm$^{-3}$) of the baked bread occurred at an oven temperature of 160 °C and oven rack speed of 20 rpm. However, the minimum density (0.26±0.01 g cm$^{-3}$) occurred at an oven temperature of 160 °C and oven rack speed of 10 rpm. Although there was no wide significant difference in the densities as depicted in Table 2. The rate at which the vapour content changes during baking might be the reason for variation in the bread densities.

The minimum density obtained is close to 0.21 g cm$^{-3}$ reported by Morakinyo et al. (2017) while evaluating the performance of the gas-fired oven. Eq. (19) shows the quadratic regression model relating the effect of oven temperature and oven rack speed on bread density.

$$\text{Bread density} = -2.037 + 0.0275x_1 - 0.00813x_2 - 0.0008x_1^2 + 0.0034x_2^2 + 0.0002x_1x_2$$ (19)

where, $x_1$ and $x_2$ are oven temperature and oven rack speed. The coefficient of determination ($R^2$) and $R^2_{(adj)}$ obtained for the model were 53.12% and 0.00%. This model is not fit to predict the effect of oven temperature and oven rack speed on bread density. This could also indicate that some other factors might be responsible for the variation in the bread density.
IV. CONCLUSION

A prototype of an electric rotary oven was developed. The performance evaluation of the rotary oven showed that the oven is efficient, with a baking capacity and baking efficiency of 16 kg h\(^{-1}\) and 94%, respectively. The oven temperature and oven rack speed had a significant influence on baking time, bread mass, bread surface area, bread specific volume and bread density. The optimum baking time for bread production was achieved in 20 min at 200 °C oven temperature and 10 rpm oven rack speed. The rotary oven is recommended for small and medium scale bakeries in developing countries.
