Abstract

Tobacco use, primarily cigarette smoking, is the leading cause of preventable morbidity and mortality in the United States, and nearly one third of those who try a cigarette become addicted to nicotine. Family physicians, who see most of these patients in their offices every year, have an important opportunity to decrease smoking rates with office-based interventions. The U.S. Public Health Service recommends that primary care physicians use the five A’s (Ask, Advise, Assess, Assist, and Arrange) model when treating patients with nicotine addiction. Physicians can improve screening and increase cessation rates by asking patients about tobacco use at every office visit. Behaviour modification can improve long-term smoking cessation success; even brief (five minutes or less) advice on smoking cessation during an office visit can increase cessation rates. The effectiveness of non-pharmacologic treatments generally is lower, therefore, pharmacotherapy is recommended for smokers who are willing to attempt cessation, unless medical contraindications exist. The pharmacologic agents approved by the U.S. Food and Drug Administration for treatment of tobacco dependence include bupropion (a non-nicotine therapy) and nicotine replacement therapies in the form of a gum, patch, nasal spray, inhaler, and lozenge. These agents have similar long-term success rates.

Introduction
Tobacco use, primarily cigarette smoking, is the leading cause of preventable morbidity and mortality in the United States. Primary care physicians have an opportunity to offer office-based smoking cessation interventions to the 70 percent of smokers who visit their offices every year. Goals of the Healthy People 2010 initiative include increasing to 75 percent the proportion of family physicians who routinely provide smoking cessation counseling. Studies have shown that physicians and their staffs can be trained to successfully deliver office-based smoking cessation interventions, and that these interventions significantly improve smoking cessation rates.

Screening and Diagnosis
The 2000 Agency for Health Care Policy and Research (AHCPR; now the Agency for Healthcare Research and Quality) clinical practice guideline on treating tobacco use and dependence urges physicians to treat tobacco use as a chronic disease. It recommends that physicians use the five A’s (Ask, Advise, Assess, Assist, and Arrange) model (Table 1) when treating patients with nicotine addiction.

The first step, asking about tobacco use at every visit, has been shown to improve screening and cessation rates; a nurse or other staff member can do this when taking the patient’s vital signs. Physicians should establish office-wide systems to enhance consistent identification of smokers. This includes asking questions to identify current, former, or never-smokers. For example, patients should be asked, “Do you currently use any form of tobacco?” Those who answer “no” should then be asked, “Have you regularly used any form of tobacco in the past?” Merely asking, “Are you a smoker?” may not identify occasional or light smokers, some of whom do not consider themselves smokers.

Treatment
One of the barriers to addressing tobacco use in the clinical setting is that physicians have not been reimbursed for much of their work in this area. In the USA, the Medicare Part B insurance plan recently began covering smoking cessation counseling. The coverage is limited to Medicare patients who have diseases or adverse health effects linked to their tobacco use and to those whose tobacco use affects their metabolism or medication dosages. More information on the coverage of tobacco use counseling is available at http://www.cms.hhs.gov/Transmittals/downloads/R618CP.pdf.

Physicians should give patients who use tobacco brief advice on why they should attempt cessation and then assess their willingness to quit. Physicians can offer motivation and support to help patients modify their behaviors. However, pharmacologic treatment has a higher success rate than nonpharmacologic treatment and should be offered to patients unless a clinical contraindication exists.

NONPHARMACOLOGIC THERAPY
The “stages of change” model is a useful tool for assessing a patient’s willingness to quit using tobacco. This model

<table>
<thead>
<tr>
<th>Five A’s</th>
<th>Implementation suggestions</th>
</tr>
</thead>
<tbody>
<tr>
<td>Ask about tobacco use during every office visit</td>
<td>Include questions about tobacco use when assessing the patient’s vital signs. Placing tobacco-use status stickers on patient charts, noting tobacco use in electronic medical records, or using computer reminder systems also may be helpful.</td>
</tr>
<tr>
<td>Advise all smokers to quit.</td>
<td>Advice should be: Clear: “I think it is important for you to quit smoking now. Cutting down or changing to light cigarettes is not enough.” Strong: “As your physician, I need to tell you that smoking cessation is one of the most important decisions you can make for your health.” Personalized: physicians should talk with patients about how smoking has affected their health, children, or other family members; the social and economic costs of smoking; and the patient’s readiness to quit.</td>
</tr>
<tr>
<td>Assess the patient’s willingness to quit.</td>
<td>Assess the patient’s willingness to quit by asking, “On a scale from 0 to 10, with 0 being ‘not at all motivated’ and 10 being ‘extremely motivated,’ how motivated are you to quit smoking?” Use the patient’s level of motivation to determine the next step: If the patient is willing to make a quit attempt, offer medication, brief counseling, and self-help resources and schedule a follow-up visit. If the patient is unwilling to quit, identify why the patient is not motivated. Explore what he or she likes and does not like about smoking and the potential advantages and disadvantages of quitting. Identify the patient’s core values (e.g., health, being a role model for children) and how smoking affects these values.</td>
</tr>
<tr>
<td>Assist the patient in his or her attempt to quit.</td>
<td>Help the patient make a quit plan: Set a quit date, ideally within two weeks of the office visit. Request encouragement and support from family and friends. Anticipate triggers and cues to smoking and identify alternative coping strategies. Help the patient change his or her environment: Throw away cigarettes, matches, lighter, and ashtrays; launder clothing; vacuum home and car. Avoid smoking in places where the patient spends a lot of time (e.g., home, work, car). Avoid other smokers and drinking alcohol. Provide basic information about smoking and cessation (e.g., addictive nature of smoking, importance of complete abstinence, possible withdrawal symptoms). Recommend pharmacotherapy, unless contraindications exist (Table 2), and behavior therapy for smoking cessation. Provide supplementary self-help materials (Table 3).</td>
</tr>
<tr>
<td>Arrange follow-up contact.</td>
<td>Follow-up should occur within the first week after the quit date. A second follow-up contact is recommended within the first month. Further follow-up visits should be scheduled as needed. During a follow-up visit, success should be congratulated. If the patient has relapsed, review the circumstances and elicit a new commitment to quit. Consider referral for more intensive treatment. Follow-up contact can be by telephone, e-mail, or in person.</td>
</tr>

30
shown to enhance motivation and predict cessation. For patients who are unwilling to quit, physicians should identify reasons for their resistance and address these reasons. Patients who are willing to attempt cessation should receive specific advice about how to proceed (e.g., setting a quit date, pharmacotherapy). Studies have shown that even brief (five minutes or less) advice on cessation from a physician during an office visit improves cessation rates compared with no advice.

PHARMACOTHERAPY

The pharmacologic agents approved by the U.S. Food and Drug Administration (FDA) for the treatment of tobacco dependence (Table 2) have similar long-term success rates. These agents include five forms of nicotine replacement therapy (NRT; e.g., gum, patch, nasal spray, inhaler, lozenge) and bupropion sustained release (Wellbutrin SR).

Nicotine Gum

A meta-analysis that included randomized controlled studies of specialized cessation clinics showed that patients using nicotine gum had higher success rates at six months than those using placebo gum (27 versus 18 percent). However, studies of general medical practices showed that the six-month success rate of nicotine gum was no different than that of placebo (12 percent). The higher cessation rate associated with nicotine gum in specialized smoking cessation clinics may be attributed to more in-depth counseling, better adherence to treatment, better trained counselors, and participants who are more motivated to quit. Nicotine gum is available over the counter in 2- and 4-mg doses. The 4-mg dose is recommended for those who smoke 15 or more cigarettes per day. No definite benefits have been noted beyond eight weeks.

Nicotine Patch (Transdermal)

A meta-analysis showed that the patch has a six-month success rate of 8 to 21 percent compared with 4 to 14 percent for placebo, and a 12-month success rate of 10 to 16 percent compared with 6 to 16 percent for placebo. Treatment beyond eight weeks has not been shown to increase effectiveness. Patches are available over the counter in 15- and 21-mg doses. Step-down doses of 14 and 7 mg may accompany the 21-mg dose, although data have not shown that this step-down approach adds benefit. Those who smoke more than 10 cigarettes per day should use the 21-mg doses. Although there were earlier concerns about the safety of nicotine patches, specifically in patients with myocardial infarction, the FDA has concluded and studies have shown that there are no adverse effects associated with the nicotine patch in smokers with a history of coronary heart disease.

Nicotine Nasal Spray

A meta-analysis showed that the nicotine nasal spray had a six-month success rate of 31 percent compared with 14 percent for placebo. One spray into each nostril equals one dose; each spray contains 0.5 mg of nicotine. Patients should use one to two doses per waking hour for three to six months. The nicotine nasal spray seems to be the most addictive of the NRTs. If a patient presents with withdrawal symptoms after abrupt discontinuation of treatment, the physician should consider initiating a four- to six-week tapering period. Tapering may be achieved by halving the dose every week. The most common side effects include nasal irritation, runny nose, sneezing, throat irritation, coughing, and watery eyes. Patients usually develop tolerance to these effects within the first week, however.

Nicotine Inhaler

A meta-analysis showed that the inhaler had a six-month success rate of 23 percent compared with 11 percent for placebo. Adverse events are generally mild and consist of throat irritation and cough. The nicotine inhaler is unique in that it mimics the hand-to-mouth motion of smoking. The inhaler consists of a cartridge attached to a plastic mouthpiece. The cartridge contains 10 mg of nicotine (but only delivers 4 mg) plus 1 mg of menthol. The recommended dose is six to 16 cartridges per day for three months, then taper for six to 12 months. The nicotine is absorbed in the mouth rather than in the lungs.

Nicotine Lozenge

Randomized clinical trials have shown that the nicotine lozenge (2 mg) has a six-week success rate of 46 percent compared with 30 percent for placebo and a six-month success rate of 24 percent compared with 14 percent for placebo. Results were similar for the 4-mg dose. The nicotine lozenge is similar to nicotine gum in that it is administered orally; however, it delivers about 25 percent more nicotine than the gum. The 4-mg dose is recommended for those who smoke their first cigarette of the day within 30 minutes of awakening; otherwise, the 2-mg dose should be used. At least nine lozenges per day are recommended for the first six weeks.

Bupropion SR

Randomized controlled trials have demonstrated that bupropion SR is effective in clinical practice settings and in hospital employees and minorities. Six-month success rates were 21 to 30 percent for bupropion SR compared with 10 to 19 percent for placebo. Common adverse effects are generally mild and consist of insomnia and dry mouth. Less common side effects include headache, nausea, and anxiety. Bupropion is contraindicated for patients with a history of seizures, anorexia or bulimia, or head trauma, and in those who currently use bupropion or monoamine oxidase inhibitors. The drug also should be avoided in patients with increased seizure risk (e.g., excessive use of alcohol or sedatives, such as benzodiazepines; addiction to opiates, cocaine, or stimulants; tight control of diabetes). Because the risk of seizure is dose dependent, the total daily dosage of bupropion SR should not exceed 300 mg.

Combination Pharmacotherapy

Combining the nicotine patch with a self-administered NRT (e.g., gum, spray, inhaler) is more effective than a single NRT. A randomized trial showed that bupropion SR combined with the patch was more effective than the patch alone but not significantly more effective than bupropion SR alone. However, a recent study including mostly veterans showed that combining bupropion SR with the patch did not significantly increase success rates compared with the patch alone. Other studies have shown that combining the patch with the inhaler or nasal spray significantly increases cessation success rates by up to 50 percent compared with the patch alone. Similarly, studies have shown that combining the patch with the inhaler or nasal spray significantly increases cessation success rates compared with each therapy alone. Therefore, combination pharmacotherapy should be considered for smokers who are unable to quit because of significant cravings or withdrawal symptoms despite adequate doses of a single therapy.

Other Recommended Pharmacotherapies

The AHCPR clinical practice guideline recommends clonidine and nor-tripti-
line as second-line agents for smoking cessation. Controlled studies on these agents are limited, and neither drug is FDA-approved for smoking cessation. Clonidine and nor-triptiline should be considered only for patients who have failed first-line therapies or are unable to use them because of contraindications.

**ALTERNATIVE THERAPIES**
A number of complementary and alternative therapies such as hypnosis and acupuncture have been considered for smoking cessation. The AHCPR did not find sufficient evidence to recommend hypnosis or acupuncture for smoking cessation. A Cochrane review of nine studies provided no evidence that hypnosis was effective for smoking cessation. Another Cochrane review of 22 randomized trials showed that there was no clear evidence that acupuncture or its variations (e.g., acupressure, laser therapy, electrostimulation) were effective for smoking cessation.

CHOOSING A TREATMENT

Few data exist comparing the effectiveness of the approved pharmacotherapies for smoking cessation. The Safety, Tolerability, Efficacy, Price, Simplicity (STEPS) approach can be used to guide physicians when they are choosing a therapy. NRTs are considered generally safe with mild adverse effects. They all have similar cardiovascular precautions, and all are pregnancy category D. Bupropion SR is also relatively safe with precautions as discussed above. However, product-specific characteristics may make some NRTs less suitable for certain patients. For example, the gum is not appropriate for patients with dental or jaw problems because it requires special chewing techniques and high frequency of use. The adhesive on the patch may be affected by humid weather. The patch also should be avoided in patients with systemic eczema. The only study that has compared the effectiveness of various NRTs reported similar results for the gum, patch, spray, and inhaler. No study has compared the lozenge with other NRTs. Although one study reported that bupropion was more effective than the patch, this finding has not been replicated. Bupropion costs slightly less than NRTs, and the patch appears to be the most convenient therapy to use among the NRTs. In one randomized controlled trial, compliance was highest for the patch (82 percent) compared with the gum (38 percent), the spray (15 percent), and the inhaler (11 percent). However, the effectiveness of these therapies may be lower in “real-world” settings because clinical trial participants are self-selected and, therefore, are more motivated to quit smoking and willing to comply with frequent follow-ups. Also, those in placebo groups typically receive substantially more counseling than those in real-world settings. These factors may produce higher quit rates in patients taking placebo than are typically found in unaided cessation attempts. Figure 5 is an algorithm for identifying and treating patients who smoke.

Follow-up

Relapse (in general or, more specifically, smoking on seven consecutive days or once each week over two consecutive weeks) is common. Physicians can use a number of brief strategies to help prevent relapse. At a minimum, patients should be encouraged to identify their smoking cues and triggers and decide on alternative coping strategies before they attempt to quit smoking. During follow-up visits, physicians should assess patients’ progress, congratulate success, and encourage continued cessation. Patients also should be encouraged to discuss the benefits of cessation including health benefits; the successes they have had (e.g., duration of abstinence, effective coping strategies); and problems or barriers to cessation (e.g., negative mood, irritability, alcohol, other smokers).

For patients who have experienced a relapse, it is recommended that the physician review with the patient the circumstances surrounding the relapse and elicit a new commitment to quit. It also is important to counsel these patients on the proper use of pharmacotherapy and to arrange a timely follow-up visit (i.e., about one week after the new quit date). Behaviour modification for smoking cessation also should be considered. Finally, patients should be reminded that a relapse is an opportunity for them to learn what tempted them to smoke and how to cope better with similar situations in the future.

On average, most smokers attempt to quit smoking four or five times before cessation is successful. Data suggest that approximately 6 to 38 percent of smokers who relapse will attempt to quit again within the next year.2 Given this relatively high rate of reattempts, it is important for physicians to maintain contact with a patient who smokes, even after relapses, to facilitate a future smoking cessation attempt when a patient is most motivated to quit. For this reason, arranging follow-up care for smoking cessation (the last step of the five A’s model) is highly important. The follow-up should occur within one week of the patient’s quit date, because the risk of relapse is highest during the first few days of abstinence. Considerable data show that additional follow-up (e.g., face-to-face contact; letters or telephone conversations; self-help materials beyond initial brief advice) significantly increases cessation success rates. Self-help brochures and print materials from professional organizations are readily available. The patient information handout with this article can be given to patients as an adjunct to initial brief advice and follow-up. In addition to office-based self-help resources, a grow-

Prognosis
Smoking cessation significantly reduces morbidity and mortality from smoking. The degree of improvement, however, depends on the disease process and the amount of damage present. Former smokers are not as vulnerable to developing coronary heart disease by 50% within one year of quitting. After four years, this risk becomes equal to that of never-smokers. The decrease in cancer risk varies with the type of cancer involved. For example, the risk of lung cancer in former smokers always remains higher than that in never-smokers. However, this risk decreases progressively and considerably with the number of years the former smoker remains abstinent. In addition to reducing morbidity and mortality, smoking cessation is among the most cost-effective measures in primary care.^

The estimated cost per life-year saved is $2,000 for smoking cessation compared with $50,000 per life-year saved for breast cancer mammography.^
