Optic neuropathy in HIV disease is due to the virus itself, para-infectious disease, opportunistic infections and drugs. Nucleoside reverse transcriptase inhibitors (NRTIs) such as zidovudine and stavudine have known mitochondrial toxicity and can cause mitochondrial myopathies, neuropathies, hyperlactataemia, and can induce mitochondrial genetic disorders. Individuals with the mutation for Leber’s hereditary optic neuropathy (LHON), a mitochondrial disorder, are usually asymptomatic but develop visual loss when exposed to external triggers such as smoking.

We report on two HIV-infected patients with LHON mutations (m.14484T>C and m.11778G>A) who developed profound visual loss with antiretroviral therapy. We postulate that the phenotypic expression of LHON in these genetically predisposed individuals was triggered by NRTI drugs lamivudine and tenofovir when used in combination, despite their relatively weak mitochondrial toxic effects.

Optic neuropathy in HIV-infected patients results from the HIV infection itself, post-infectious auto-immune disease, opportunistic infections and drugs. Hence it is no surprise that visual loss from optic nerve disease is common in patients infected with HIV. Epidemiological studies are lacking, especially in South Africa (SA) where the prevalence of HIV is high.

The causes of HIV-associated optic neuromopathies that are commonly encountered in clinical practice are listed in Table 1. The immune-mediated optic neuromopathies are para-infectious and occur in the setting of seroconversion or as part of acute disseminated encephalomyelitis when CD4⁺ counts may be relatively normal; these often respond to intravenous steroid therapy. Infectious and lymphomatous optic neuromopathies occur during advanced stages of immunocompromise when CD4⁺ counts are low; in such patients, identifying an infective cause is urgent to prevent blindness. Ethambutol-associated retrobulbar optic neuropathy is common, especially in disseminated tuberculosis where its prolonged use over 9 months is advocated.

The optic nerve is unique as it is a white matter tract that is particularly susceptible to physical, ischaemic, toxic and hypoxic insults due to: its relatively large diameter (1.2 million axons per nerve); its intra- and extra-cranial location; its myelinated and unmyelinated segments; and the high energy demand by the retinal ganglion cells. The large accumulation of mitochondria within the optic nerve head is mostly responsible for its energy supply. The function of these mitochondria is disturbed in the setting of Leber’s hereditary optic neuropathy (LHON), where gene defects from base substitutions at 11778G>A, 14484T>C and 3460G>A...
cause optic nerve dysfunction in over 95% of patients by disrupting complex 1-dependent adenosine triphosphate synthesis. The abnormal mitochondrial gene is maternally inherited with incomplete penetrance, as only 50% of males with the LHON mitochondrial mutation present with the disorder. Expression of the disease occurs when triggered by environmental factors such as smoking, alcohol and acute illness. The typical presentation is sequential or bilateral, simultaneous central visual loss in the 2nd to 3rd decade of life in males carrying one of the LHON mitochondrial missense mutations. Ten per cent of female carriers are symptomatic. There is initial disc swelling and circumpapillary telangiectasia, which within a few months are replaced by optic atrophy from axonal loss. Visual loss and centro-caecal scotomas progress over months to years. Idebenone, a co-enzyme Q10 derivative, has shown promise in delaying the progression of illness and in some cases substantially reversing the visual and field loss.

We present two patients from our neuroophthalmology unit who presented with central visual loss after starting antiretroviral therapy containing tenofovir, lamivudine and efavirenz.

**Patient 1**
A 31-year-old HIV-infected man presented with a 4-month history of gradual and progressive loss of bilateral vision. He denied having headaches, pain on eye movements or constitutional symptoms. He was previously unemployed. Two years before, he acquired pulmonary tuberculosis and was found to be HIV-infected; he was then prescribed antiretroviral therapy containing tenofovir, lamivudine and efavirenz. He had no family history of visual loss.

His visual acuity was ‘counting fingers’ on the right and ‘hand movements’ on the left. Central field defects were detected bilaterally on confrontation, but were globally lost on automated Humphrey visual field (HVF) testing. Colour vision was severely impaired bilaterally (0/15 on Ishihara pseudoisochromatic plates). Both pupils were sluggishly reactive and severe bilateral optic atrophy was present on funduscopy (Fig. 1). The visual evoked potential (VEP) P100 waveforms were obtainable bilaterally using goggles, but were markedly reduced in amplitude.

Magnetic resonance imaging (MRI) of the brain and orbits was normal. Chest radiograph and cerebrospinal fluid (CSF) examination, including neurotropic virus (cytomegalovirus, herpes simplex viruses 1 and 2, varicella zoster virus, Epstein-Barr virus and John Cunningham virus) testing were unremarkable and routine haematological investigations were normal. His vitamin B<sub>12</sub>, folate and iron levels were normal. CD4<sup>+</sup> cell count was 746 cells/µl and viral load was undetectable. The antinuclear factor (ANF), antineutrophil cytoplasmatic antibody (ANCA), rapid plasma reagin (RPR) and rheumatoid factor (RF) were negative, and serum angiotensin converting enzyme (SACE) was 19 U/l. Oligoclonal bands (OBs) were not detected in the CSF and aquaporin 4 antibodies were negative. He tested positive for the 14484T>C mitochondrial mutation associated with LHON.

**Patient 2**
A 33-year-old HIV-infected man who worked in construction presented with bilateral visual loss over the previous 3 years. He had been diagnosed with HIV infection after voluntary testing and prescribed tenofovir, lamivudine and efavirenz 3 months before the onset of his visual symptoms. He first noticed loss of central vision in the left eye, followed by similar symptoms in the right a month later. He denied any colour desaturation and pain on eye movements, but did notice intermittent oscillopsia at the onset of his symptoms. He had no other medical history of note and denied any smoking or alcohol use, exposure to any toxins or substance abuse. He had no family history of visual loss.

His visual acuity bilaterally was ‘counting fingers’. Central scotomas were noted on confrontation, but HVF showed bilateral, inferior altitudinal field defects. Colour vision was severely impaired (0/15 on Ishihara pseudoisochromatic plates) and funduscopy revealed bilateral profound optic atrophy (Fig. 2). His pupils were reactive and a 1+ relative afferent pupillary defect was present on the right. The rest of his neurological examination was normal, and standard haematological, biochemical and CSF examination tests were normal. His CD4<sup>+</sup> count was 615 cells/µl and viral load was 27 copies/ml. MRI of the brain and orbits was normal, as was his chest radiograph. The VEP P100 wave amplitudes were reduced bilaterally. His vitamin B<sub>12</sub> level was mildly reduced at 117 pmol/l (normal 133 - 675), serum folate was normal and SACE was

postulate that in the genetically susceptible individual, tenofovir has the potential to trigger LHON.

Idebenone (co-enzyme Q10 derivative) is not available in SA. However, co-enzyme Q10 is available as an over-the-counter preparation at most pharmacies. Both patients were treated with this formulation and have not shown any deterioration or improvement after 6 months of treatment. ART was discontinued in both patients and when required, both patients will be considered for a combination of antiretrovirals with lower mitochondrial toxicities, such as protease and integrase inhibitors.

Conclusion

LHON can be triggered by NRTIs in HIV-infected patients who harbour the LHON mutations. The expression of LHON can occur regardless of the mitochondrial toxic potential of ART. The routine screening for LHON mutations on all asymptomatic male patients about to commence NRTIs is not cost effective. However, the progression of LHON is reasonably manageable with appropriate therapy; hence testing for LHON mutations in HIV-positive patients with optic neuropathy who are on ART should become standard practice.
