Cutaneous adverse drug reactions (CADRs) are a common complication of antiretroviral therapy and of drugs used to treat opportunistic infections. We present a rare case of acute generalised exanthematous pustulosis secondary to cotrimoxazole or tenofovir.

Cutaneous adverse drug reactions are a common complication of antiretroviral therapy and of drugs used to treat opportunistic infections. The common clinical manifestations range from mild maculopapular eruptions to the more severe recognised spectrum of Stevens-Johnson Syndrome (SJS), toxic epidermal necrolysis (TEN) and drug reaction with eosinophilia and systemic symptoms (DRESS). Occasionally, however, a rare manifestation of CADR occurs which presents a diagnostic dilemma.

Case report

A 24-year-old South African woman was newly diagnosed with disseminated culture-positive tuberculosis (TB) and HIV. Her CD4 count was 77 cells/mm³ and she had no prior TB history (including contacts). The patient was initiated on Rifafour, and cotrimoxazole prophylaxis was started 9 days later. After a further 2 weeks, ART was initiated (tenofovir (TDF), lamivudine and efavirenz).

One month after ART initiation, the patient presented with sudden-onset generalised, pustular, itchy rash, associated with 1 week of fatigue, nausea, vomiting and painful feet. She had renal impairment (creatinine 521 µmol/l) and was anaemic (haemoglobin 6.1g/dl). Treatment with TDF, cotrimoxazole and rifampicin was ceased, and the patient was referred for further assessment.

On examination, she was tachycardic but apyrexic. She had a widespread pustular rash sparing the palms and soles (Fig. 1). Pustules were <5 mm in size and monomorphic on an erythematous background, with areas of desquamation on the lower limbs. She had no mucous membrane involvement, but had manifested angular cheilitis and oral candidiasis. Tender hepatomegaly and painful, peripheral sensory neuropathy were noted.

A pus swab from one of the lesions showed neutrophils, but Gram-stain and culture testing were both negative. Testing of a pustule aspirate for varicella zoster virus by polymerase chain reaction (PCR) was also negative. Blood, urine and sputum bacterial cultures were negative, as was syphilis serology, serum cryptococcal latex antigen test and hepatitis B serology. In addition to anaemia, the patient had a leucocytosis of 11.5 x 10⁹/l (93% neutrophils), but her platelet count was normal. She was hypo-albuminaemic (19 g/l) with mild liver dysfunction (total bilirubin 23 µmol/l, alkaline phosphatase 171 U/l, gamma-glutamyl transferase 111 U/l, alanine transaminase 34 U/l and aspartate transaminase 58 U/l). A chest X-ray showed diffuse bi-basal nodularity. Necrotic lymph nodes and multiple splenic hypodensities, suggestive of abdominal TB, were evident on abdominal ultrasound.

Two days after admission, treatment with abacavir was started to replace TDF, and the patient was started on
rash had considerably improved after 8 days and her creatinine level diminished to 303 μmol/l. Renal biopsy was delayed due to the overlying skin lesions.

Histopathology of a skin biopsy on admission showed basket-weave hyperkeratosis, spongiosis and an intracorneal pustule, containing neutrophils and occasional lymphocytes (Fig. 2). Small cocci were noted within the pustule and a mild superficial perivascular lymphocytic infiltrate was present. Superficial dermal vessels were mildly dilated and contained margined neutrophils. Special stains for fungi and acid-fast bacilli were negative and no granulomas, dysplastic or malignant cells were found. A histopathological diagnosis of acute generalised exanthematous pustulosis (AGEP) was made.

Multi-drug resistant TB (MDR-TB) was subsequently diagnosed on the basis of a urine culture (sampled on admission) and her TB regimen was altered. She was discharged with a clinical diagnosis of acute kidney injury secondary to TDF, disseminated MDR-TB, and AGEP most likely secondary to cotrimoxazole or TDF. She has had a good clinical response and, at the time of writing, remains in care 7 months post discharge.

**Discussion**

AGEP is an uncommon severe cutaneous reaction associated with drug exposure in 90% of cases. The remaining 10% of cases have been attributed to viral infections, vaccines, spider bites, heavy metal exposure, chemotherapy and radiation.2 The reaction has a mortality rate of 2%, typically occurring in the elderly with co-morbidities, and is related to septic complications.2 A wide spectrum of pustular skin diseases forms the differential diagnosis, including pustular psoriasis, Sweet’s syndrome (acute febrile neutrophilic dermatosis), pustular erythema multiforme, TEN, DRESS and bullous impetigo.3,4 In our patient, disseminated varicella was also considered. The combination of clinical and histological features together with appropriate drug exposure is usually enough to make the diagnosis of AGEP.1,3

To date, a single case of AGEP has been described in an HIV-infected patient with a CD4 count of 220 cells/mm³, attributed to boosted darunavir, which recurred on atazanavir re-challenge.1 Protease inhibitors (indinavir and boosted lopinavir) have also been implicated in AGEP in patients receiving post-exposure prophylaxis.1,2 Nucleoside/nucleotide reverse transcriptase inhibitors have not been implicated as causal agents. However, there are case reports of AGEP following cotrimoxazole treatment in HIV-negative patients.4,5

The pathophysiology of AGEP involves drug-specific T cell activation by dendritic cells followed by T cell expansion and migration to the dermis and epidermis. The T cells are activated to produce high levels of neutrophil-attracting chemokine (CXCL8) and express a type 1 T-helper (Th-1) cytokine profile (granulocyte-macrophage colony-stimulating factor, interferon gamma and tumour necrosis factor-alpha). Stimulated keratinocytes recruit T cells and neutrophils to the inflamed skin. Drug-specific cytotoxic CD8 T cells are responsible for killing keratinocytes and for vesicle formation, while neutrophils migrate along the CXCL8 gradient into the vesicles to form pustules.6 In the case described here, the delayed presentation following initiation of cotrimoxazole, the most likely causative agent, may have been attributed to reduced drug-specific T cell activation in advanced HIV disease.

Characteristic features of AGEP include an acute generalised cutaneous eruption of whitish non-follicular, sterile pustules <5 mm in size and on a background of erythema, which may be accompanied by a burning sensation. Lesions often start on the face or intertrigenous areas, moving to the trunk and limbs within a few hours. The reaction rarely affects the palms and soles and has mucous membrane involvement in only 20% of cases. Half of affected patients may report other skin symptoms. The rash lasts for a mean of 9.4 days (range 4 - 10), followed by desquamation. The rash is accompanied by a fever >38°C that lasts for approximately 1 week.7 The onset of rash follows 2 distinct patterns: (i) a rapid onset after drug ingestion (a few hours to 2 - 3 days) which is most commonly associated with antibiotics and may signify previous sensitisation; and (ii) an onset after 1 - 3 weeks (mean 11 days), which may result from primary sensitisation.1,4

A neutrophilia occurs in 90% of cases, while up to 30% have mild eosinophilia. Renal dysfunction (predominantly pre-renal) occurs in one-third of cases. Rarely, hypocalcaemia and a mild elevation in amino-transferases have been observed.2,5 The skin biopsy is characterised by spongiform subcorneal or intradermal pustules, papillary oedema and neutrophilic perivascular infiltrates.1,5

When there is doubt over the causal agent, and there are no alternative therapeutic agents,
confirmatory tests may be performed under specialist supervision:

- Drug provocation testing: although the gold standard for CADR, this is contra-indicated in AGEP.10
- Patch testing: although this has only a 50% sensitivity and 85% specificity, it is the best available test for practical reasons.2
- The lymphocyte transformation test (LTT): requires a specialised laboratory, but has an improved sensitivity of 78% with varying specificity.3

Treatment of AGEP is symptomatic, with withdrawal of treatment with the offending drug. Antibiotics are not indicated unless secondary infection occurs. Corticosteroid treatment has been used, but is not required in the majority of cases.5

**Conclusion**

This case highlights a rare adverse drug reaction that can occur in HIV-infected patients and is an important differential diagnosis of a pustular eruption. Antibiotics are the most common causative agents, and protease inhibitors are the most commonly implicated ART drugs. Early recognition and drug withdrawal are vital. If drug re-challenge is required, this should be done under specialist supervision.
