Poor adherence to South African guidelines for the management of community-acquired pneumonia

K Nyamande, U G Laloo

Objective. To evaluate adherence to the South African guidelines for the management of community-acquired pneumonia (CAP) and to determine whether adherence reduced length of hospital stay and mortality in patients with severe CAP.

Setting. King Edward VIII Hospital, Durban.

Methods. Four hundred and thirty patients with CAP were recruited between June 2000 and October 2001. Severity assessment data were collected. Severe CAP was defined by the presence of two or more markers. Without influence from the investigators, the admitting team chose the empirical antibiotic regimen. Antibiotics administered, outcome and length of stay were analysed.

Results. Two hundred and eighty-seven of 430 patients were eligible for analysis. One hundred and eighty-two patients had two or more markers of severe CAP. Fourteen of the 182 patients (8%) had initial antibiotic therapy administered according to South African guidelines and 168 (92%) did not. The mortality rate was 20% (36 patients). Accounting for sample size there was no statistically significant difference in length of stay between the two groups (14 v. 12 days, \( p = 1.0000 \), odds ratio (OR) 1.167, 95% confidence interval (CI): 0.3926 - 3.467) or in mortality rate (28.5% v. 19%, \( p = 0.3549 \), OR 1.667, 95% CI: 0.667 - 4.161).

Conclusion. There was very poor adherence with South African CAP antibiotic guidelines. The sample size of patients receiving treatment according to the South African Thoracic Society (SATS) guidelines was too low to confirm confidently that adherence may have resulted in a clinical benefit.

hundred and fifty-three of the 182 patients (84%) were HIV infected. The excluded 248 patients did not meet the criteria for severe disease, or had proven *Mycobacterium tuberculosis*, PCP, fungal pneumonia or were being treated empirically for PCP or PTB. The proportion of patients with each parameter considered as a marker of severe disease were: age > 60 years (2% of patients), co-morbid disease (9%), confusion (0%), hypotension (1%), involvement of 2 or more lobes (58%), respiratory rate ≥ 30 breaths/min (59%), temperature ≥ 38.3°C (53%), partial pressure of arterial oxygen < 60 mmHg (8%), white cell count < 4 x 10^9 cells/mm^3 or > 30 x 10^9 cells/mm^3 (9%), urea > 7 mmol/l (49%) and albumin < 30 mmol/l (82%). A total of 113 bacterial isolates were identified, 50% of these were *Streptococcus pneumoniae*. Atypical pathogens accounted for 21% of isolates.

Empirical antibiotic treatment for severe CAP consistent with South African guidelines was administered to 14 patients (8%) only. The remaining 168 patients (92%) were given treatment that was inconsistent with the guidelines. In the cohort of patients in whom the guidelines were followed, 9 subjects received intravenous second-generation cephalosporin and an aminoglycoside, 4 patients had intravenous amoxicillin-clavulanic acid and an aminoglycoside, and 1 patient received intravenous second-generation cephalosporin and a macrolide. In the cohort in which the guidelines were not followed, antibiotic regimens administered were as shown in Table I.

Thirty-six patients died, resulting in an overall mortality rate of 20%. Four patients (28.5%) died in the group that received treatment consistent with the South African guidelines while 32 patients (19%) died in the cohort whose antibiotic regimens were not consistent with the guidelines. The difference in mortality was not statistically significant (*p* = 0.7106).

There was no statistically significant difference in the mean length of hospital stay between the two cohorts. However, as only 14 of 182 patients were treated according to guidelines, the sample size may be too small to detect meaningful difference. The length of stay in both groups (14 days and 12 days respectively) is a reflection of the severity of illness combined with socio-economic deprivation. Besides the severity of illness, the high HIV seropositivity rate of 84% is an important consideration. Patients tend to have a multiplicity of problems such as wasting, general debilitation and dehydration.

Mortality was 28.5% and 19% in the patients who were given treatment consistent with and inconsistent with South African guidelines respectively. Although the group in which the guidelines were not followed appeared to have had a better outcome, this difference did not reach statistical significance (*p* = 0.7106). One factor that might have influenced these results is the small number of patients in the group who received treatment according to the published guidelines. A potential weakness of this study was the non-application of multiple logistical regression models to the confounding variable to

### Table I. Physicians’ antibiotic choices in the cohort of patients whose antibiotic regimens were not consistent with the South African guidelines (N = 168)

adjust for the differences in mortality and length of stay in the two groups.

The study has shown that the South African guidelines have failed to significantly influence medical practice at a tertiary teaching hospital. There are several possible explanations. These include lack of awareness, attitude, lack of knowledge of the guidelines and local barriers to implementation of the guidelines. In addition, physicians may feel that guidelines restrict their autonomy, freedom and clinical judgement. Possible solutions include continuing medical education, feedback and physicians’ participation in efforts to have guidelines adopted and implemented, participation of administrators as well as regular guideline revision and auditing. Guidelines need to be flexible and to be scientifically validated.

This study brings into focus the issue of institutional policy regarding the use of antimicrobials. There is no institutional policy on the use of antibiotics in CAP within the medical domain at King Edward VIII Hospital. The failure to provide clear policy may be owing to various reasons including ignorance of the need for and advantages of well-formulated policies, fear of alienating professionals, a lack of or shortage of good managers, inadequate financial resources which might make such policies unworkable, and bureaucratic and political interference. Sound working relationships between institutional managers and clinicians are necessary for any policy to work. Erratic supplies of drugs would render any institutional policies unworkable. In the light of the data on compliance from this study, it is important to get some feedback from the clinicians regarding guidelines in general and the CAP guidelines in particular. This could be a follow-up study in the form of a questionnaire. Valuable data on knowledge, attitudes, fears, concerns and antibiotic practising habits could emanate from such a study. The study could provide answers for the poor adherence to the guidelines.

The South African Thoracic Society (SATS) CAP guidelines were recently revised. Clear, workable strategies need to be devised to disseminate these guidelines to practising clinicians in an efficient and cost-effective manner. If the data from this study is a reflection of practice country-wide, a lot of work would be required to change physicians’ practising habits. Although it may be argued that mortality is not necessarily altered by following guidelines, there are equally compelling reasons for the issue of guidelines to be pursued vigorously. These are cost effectiveness, rational prescribing and minimising the development of antibiotic resistance, among other reasons. Lastly, the revised SATS CAP guidelines emphasise the emergence of tuberculosis and PCP as common pathogens in the light of the HIV epidemic.

In conclusion, we have shown poor adherence to the CAP guidelines. A larger national multicentre study is required to validate current guidelines. Future studies should also focus on the reasons for non-compliance and the economic implications.
