the CaO2. Although a change in FiO2 will only have a small effect on the CaO2, and hence oxygen delivery, an increase in the inspired fraction of oxygen from 0.21 to 1 will translate into an approximately 10% increase in CaO2. Given that the CaO2 is a mathematical combination of the CO2 and CaO2, this will lead to modest increases in total oxygen delivery. At a constant VO2, this will result in an increase in the PVO2, and thus affect the AaDO2. This theoretical view has been confirmed by Douglas et al.2

The effect of positive end-expiratory pressure (PEEP) on the increase in AaDO2 as the FiO2 increased, has not been directly examined.6 When the effect of PEEP on the Qs/Qt was examined, conflicting results were reported. One study demonstrated that PEEP prevented the increase in Qs/Qt as the FiO2 was increased while another failed to confirm this observation.7 First impressions suggest that the stabilising effect of PEEP should overcome the tendency of alveoli to collapse. One can, however, speculate that the alveoli with the lower ventilation-perfusion ratios (lower alveolar volume) are the least compliant and will therefore only benefit at a later stage of PEEP application, compared with the more compliant alveoli which will absorb the early PEEP. If this speculation is correct, then the alveoli with low ventilation-perfusion ratios at risk of collapse during denitrogenation are the alveoli that will benefit the least from PEEP. Also, PEEP could impede cardiac output and have an effect via the decrease in PVO2.

Data from this study seem to indicate that the commonly used indices do not accurately reflect the Qs/Qt of the injured lung. Also, the FiO2 had an effect on some of these indices. The so-called less invasive indices should therefore be applied with the necessary circumspection and comparison should, at least, be made at a similar FiO2.

**Congenital syphilis associated with persistent pulmonary hypertension of the neonate – a clinicopathological case study**

Johan Smith, Johann W. Schneider

Congenital syphilis remains a significant clinical problem, especially in developing countries. We report a fatal case of congenital syphilis complicated by persistent pulmonary hypertension and hypoxic ischaemic encephalopathy.

**Objective.** To describe the association of congenital syphilis with persistent pulmonary hypertension of the newborn (PPHN).

**Method.** Case report of a single patient.

**Results.** Fatal outcome of one baby with congenital syphilis and associated PPHN despite maximal conventional treatment. Histological examination of the lungs revealed pulmonary oedema, intra-alveolar haemorrhages, localised bronchopneumonia and marked interstitial infiltrates of lymphocytes, plasma cells, macrophages and fibroblasts with interstitial fibrosis. Examination of peripheral pulmonary arteries revealed focal excessive muscularisation with increased adventitial connective tissue.

**Discussion.** Reviewing our own experience and available literature, this case study supports the infrequent association of congenital syphilis with PPHN. However, when it occurs, this combination appears to be fatal.

**Conclusion.** More research is warranted to clarify the role of inflammatory mediators in congenital syphilis of the lung.

Although more common in underdeveloped and developing countries, congenital syphilis occurs among all social groups.14 The spectrum of the disease varies from stillbirths and asymptomatic infected liveborn infants to overt syphilis-associated multisystem involvement.14 Apart from the classic clinical manifestation, unfamiliar disorders have been reported to occur in association with congenital syphilis.

These include neonatal intestinal obstruction with or without ileal perforation, non-syndromic paucity of intrahepatic bile ducts and necrotising funisitis. Recently, Spear et al. described the first (to our knowledge) case of persistent pulmonary hypertension of the neonate (PPHN) with respiratory failure, associated with congenital syphilis. We report a neonate who presented with congenital syphilis-associated PPHN and superimposed intra-uterine hypoxia, illustrating the varying spectrum of clinical circumstances in which congenital syphilis should be a diagnostic consideration.

Case history

The patient, a male infant weighing 2520 g, was the product of 38 weeks' gestation in a 34-year-old gravida 9, para 8 woman. The mother did not attend antenatal clinics and presented on the day of delivery in active labour. On examination, abdominal palpation revealed a singleton breech presentation. The cervix was 3 cm dilated and the membranes were intact. External fetal heart rate monitoring showed a basal heart rate of 150/min with extremely poor beat-to-beat variability of less than 5/min. Repeated late decelerations occurred. A lower uterine segment caesarean section was performed, yielding an infant with Apgar scores of 2 and 6 at 1 and 5 minutes, respectively. No meconium was noted. The placenta appeared large and weighed 700 g. The infant was intubated and ventilated. The initial physical examination revealed a hydropic and pale-looking infant. His abdomen was distended because of ascites and hepatosplenomegaly. Widespread skin desquamation and a truncal petechial rash were evident. Decreased capillary filling time, weakly palpable pulses, hypotension (blood pressure 40/19 mmHg) and active bleeding via the endotracheal tube were observed. Neurological findings included a depressed level of consciousness and generalised intermittent tonic seizures.

The initial chest radiograph (Fig. 1) showed interstitial lung involvement, right upper lobe opacification and an increased cardiothoracic ratio (0.64). The initial arterial blood gas analysis on a FiO₂ of 1.0 revealed the following: pH 7.17, partial arterial carbon dioxide pressure (PaCO₂) 5.5 kPa, partial arterial oxygen pressure (PaO₂) 7.0 kPa, bicarbonate 16 mmol/l, and an arterial-alveolar PO₂ ratio (a/APO₂) of 0.07. (The a/APO₂ ratio reflects the degree of compromise in arterial oxygenation and the ratio in a healthy baby is > 0.75.) The full blood count revealed a white cell count of 35 x 10⁹/l (neutrophils 18%, lymphocytes 66%, monocytes 6%, eosinophils 4%, band cells 2%, basophils 2%, metamyelocytes 2%); the haemoglobin concentration was 8.9 g/dl; the mean corpuscular volume (MCV) was 120 fl; and platelet count 43 x 10⁹/l. The liver enzyme values were as follows: aspartate aminotransferase (AST) 287 U/l, alanine aminotransferase (ALT) 45 U/l, lactate dehydrogenase (LDH) 1931 U/l and alkaline phosphatase 372 U/l. The C-reactive protein level was 31 mg/ml and the infant's venereal disease research laboratory (VDRL) titre was 1:256. Fluorescent treponemal antibody absorption (FTA-ABS) and FTA-ABS IgM testing confirmed congenital syphilis. Other investigations revealed no laboratory evidence of cytomegaloviral or toxoplasmosis infection. The infant's clinical course was complicated by severe PPHN and status epilepticus. The PPHN was confirmed by two-dimensional echocardiography which showed right-to-left shunting across the ductus arteriosus, tricuspid insufficiency and an estimated pulmonary artery systolic pressure of 48 mmHg. The pulmonary arterial hypertension initially responded to hyperventilation-induced alkalosis. No tolazoline or exogenous surfactant was administered. Further treatment included penicillin, dopamine, intravascular volume expansion and a continuous bicarbonate infusion. The ventilatory course of the patient is depicted in Fig. 2. The ventilation index (V11), the product of ventilator respiratory rate and peak inspiratory pressure partly reflects severe respiratory compromise (V11 > 1000) and our approach to ventilation in some patients with PPHN, i.e. hyperventilation (higher V11) to induce an alkalosis in an attempt to reduce pulmonary vascular resistance with subsequent improvement in oxygenation (higher a/APO₂ ratios). In Fig. 2, the effect of this approach on oxygenation is most evident at 18 hours of age. Despite attempts to stabilise the infant,
there were marked fluctuations in oxygen saturations (depicted in the a/FIO2 ratio changes) which coincided with recurrent convulsions. The convulsions were resistant to all forms of treatment including phenobarbitone, phenytoin, continuous lignocaine infusion and pentothal.

Ultrasonographic studies of the brain demonstrated bilateral subependymal intracranial haemorrhages without hydrocephalus or brain swelling. In the light of the severe respiratory compromise and status epilepticus it was decided to withdraw life support therapy. The patient died 37 hours after birth.

Autopsy showed lungs of normal macroscopic size. There was a slightly increased combined lung mass of 46.5 g. Histopathological examination of lung sections (Fig. 3) revealed pulmonary oedema, intra-alveolar haemorrhages, localised bronchopneumonia and a marked interstitial infiltrate of lymphocytes, plasma cells and macrophages associated with fibroblast proliferation and mild interstitial fibrosis. Close examination of the peripheral pulmonary arterioles within the inter-alveolar septa showed focal muscularisation with associated increased adventitial connective tissue. These changes were observed in numerous sections representative of all the lung lobes. Meconium aspiration, intravascular thrombi and abnormalities of the pulmonary veins were absent. No evidence of obliterative fibrosis as described in ‘pneumonia alba’ was present.

Fig. 3. The inter-alveolar septa are infiltrated by numerous macrophages, lymphocytes and plasma cells (inset) with associated fibroblasts and delicate fibrosis. Note the muscularisation of an intra-acinar arteriole (arrows)

Examination of the cardiovascular system revealed a patent foramen ovale and a ductus arteriosus. The brain showed no evidence of syphilitic involvement. A subependymal matrix haemorrhage without ventricular dilatation was present. Sections of the pancreas, hypothysis, epididymis, pharynx, submucosa of the small intestine, adrenals, kidneys and pericardium showed extensive interstitial fibrosis and inflammation.

Extramedullary haematopoeisis was a prominent finding in the liver, spleen, myocardium, lungs, adrenals and pancreas. The placenta was unavailable for histological assessment.

Discussion

PPHN remains a challenging clinical problem. The incidence varies, but accounts for 1 - 4% of all neonatal intensive care unit admissions per year.12 The clinical syndrome is characterised by severe hypoxaemia due to right-to-left shunting of blood through the ductus arteriosus and/or foramen ovale. Symptoms usually appear soon after birth in affected full-term or post-term babies.13 However, in developing countries, babies with this condition tend to be of both lower birth weight and gestational age.14 PPHN was previously noted to occur equally frequently (50:50) with or without underlying lung disease. During the past 9 years, reports clearly show a shift towards a 25:75 ratio in favour of PPHN’s occurring in association with lung disease or cardiac anomalies.13 The change particularly seems to reflect increasing awareness of PPHN associated with diseases such as hyaline membrane disease and pneumonia caused by a variety of organisms.13 - 17

Both animal studies and human case reports indicate that increased pulmonary vascular resistance occurs in association with Gram-negative organisms (Pseudomonas spp., Escherichia col), group B Streptococcus, Pneumococcus and Ureaplasma urealyticum infections.16 - 17 In cases of neonatal sepsis it has been suggested that PPHN might be mediated or exacerbated by endogenous thromboxane A2 release. Urinary metabolite (dinorthromboxane B2) excretion was found to be consistently higher early in the course of pulmonary hypertension associated with sepsis, compared with hypertension without sepsis.18

Recently, Waites et al.17 described 5 babies who suffered from U. urealyticum pneumonia associated with PPHN. Four of the 5 infants also had other concomitant bacterial infections, including Staphylococcus epidermidis, Mycoplasma hominis and a Haemophilus species. Nevertheless, both U. urealyticum and M. hominis have been shown to produce phospholipases which may be involved in the pathogenesis of PPHN via the liberation of arachidonic acid and subsequent thromboxane.18

In some cases, the sequence of events resulting in clinical PPHN suggests that perinatal hypoxia could have been the underlying ‘trigger’. It is possible that thromboxane, released as a result of hypoxia, may mediate both platelet aggregation and pulmonary hypertension.19 There are considerable data to show that the pulmonary vasculature undergoes extensive remodelling in cases of smooth-muscle cell hyperplasia and that there is an increase in connective tissue when it is exposed to chronic hypoxia.20 The pathogenesis of the cellular hyperplasia is unclear, but may involve vascular endothelial injury, smooth-muscle cell and fibroblast interaction.21,22 Pulmonary parenchymal involvement in infants with congenital syphilis is common and is a difficult problem to manage.23 In premature babies with syphilis, the lung disease indicates a combination of surfactant deficiency, lung immaturity, interstitial scarring and extramedullary haematopoeisis; it is slow to resolve. The pulmonary involvement in the present case demonstrated a combination of pathological findings of which lymphocyte, macrophage and plasma cell infiltration of the interstitium was the most prominent. In addition to this, and previously
unreported, excessive focal intra-accinar arteriolar 
muscularisation was shown. It is not clear from the 
present case whether asphyxia and/or syphilis infection per se led 
to the development of the pulmonary hypertension. The 
evidence that hypoxia played a role is convincing (late 
decelerations, low Apgar score, severe metabolic acidosis at 
birth, hypoxic ischaemic encephalopathy). A review of 
the records of 37 infants with congenital syphilis who were 
admitted to our neonatal intensive care unit (1984 - 1991) 
revealed no documented PPHN (unpublished data).

The role of chemical mediators of inflammation and 
fibroblast proliferation released by macrophages and 
lymphocytes in the neonatal lung in cases of congenital 
syphilis has not been studied. Apart from the role of 
hypoxia, no hypothesis adequately explains the 
pathogenesis of treponemal infection of the neonatal lung. 
Despite the evidence for an immunopathy’s causing 
syphilitic placentitis, we were unable to detect the typical 
vasculitic changes in the lung characteristic of a type III 
immunological reaction. It is therefore unclear what 
pathogenetic role non-organ-specific serum auto-antibodies, 
such as rheumatoid factor or circulating immune complexes, 
play in the development of lung disease in babies with 
syphilis.24-28 Polymorphonuclear leucocytes infiltrate within 
1 - 2 days following testicular injection of Treponema 
pallidum in rabbits. Serum immunoglobulin G is first 
detectable on day 3 and interleukin-2 (IL-2) is activated by 
day 4.29 T lymphocytes infiltrate and proliferate by day 6.28 
Macrophages subsequently infiltrate infected tissues and 
phagocyte and secrete treponemalnic factors that kill 
and lyse T. pallidum in the presence of opsonic antibody.27,28,29 
Fitzgerald28 recently suggested that T. pallidum stimulates 
IL-2 production, delayed-type hypersensitivity reaction and 
gamma interferon production (Th response) which up- 
regulate phagocytosis by macrophages. Subsequent 
oversecretion of prostaglandin E2 by macrophages interrupts 
the continued cycle of macrophage activity (through 
inhibition of T-helper cell synthesis of gamma interferon), 
eventually culminating in chronic infection. Macrophages 
also release several mediators that stimulate lung fibroblast 
proliferation. Of these fibronectin, platelet-derived growth 
factor and insulin-like growth factor 1 are implicated in 
the continued cycle of macrophage activity (through 
production in the pathogenesis of prenatally acquired 
PPHN is a rare finding. This combination also appears 
to be poorly responsive to conventional therapeutic 
manoeuvres. Further research is warranted to clarify the 
potential role of inflammatory mediators, circulating immune 
complexes, vascular endothelial damage and prostanoid 
production in the pathogenesis of prenatally acquired 
syphilitic lung disease associated with PPHN, before the 
"great imitator" is definitely implicated as a cause of PPHN.
