against the operative mortality of gastrectomy. There is little doubt that in our set-up a very strong case can be made for elective surgery in benign gastric ulcer.

**RECOMMENDED PROGRAMME**

In view of the above, surgical treatment is recommended for the following:

1. All gastric ulcers which are complicated or have been complicated. The operation may have to be an emergency procedure or carried out electively 1–2 months later.
2. Gastric ulcers complicating duodenal ulceration.
3. ‘GIant’ gastric ulcers, i.e. over 4 cm in size. A short course of preoperative medical treatment is advisable.
4. Gastric ulcers in patients with a history of previous hospitalization for the same complaint. By the same token, an ulcer which recurs after successful medical treatment should be operated upon.
5. If there is any suspicion of malignancy on full investigation by barium meal, acid-output studies, gastroscopy, gastrocameras, gastric cytology and peroral gastric biopsy. If all investigations are negative for carcinoma but there is still clinical suspicion, surgery is recommended especially if the MAO is less than 5 mEq/hour.
6. If controlled medical treatment fails.

Controlled medical treatment is indicated only if, after a full work-up, there is no suspicion whatsoever of malignancy. ‘Controlled’ implies:

1. That the patient is kept under strict observation.
2. That a repeat barium meal is done after 2 weeks. The crater of an uncomplicated benign ulcer will reduce by 50% in size during this time. Failure to obtain such a response will prompt many surgeons to operate without further delay and I would agree with this if the patient still has symptoms. However, we are usually prepared to wait another month for the next step, viz.:
3. That a repeat barium meal and gastroscopy are done after 6 weeks of treatment. Uncomplicated benign gastric ulcers will heal in this time. If healing as determined by barium meal and gastroscopy is not complete, the ulcer is presumed to be either complicated or malignant and operation is, therefore, performed without further delay.

The elective procedure of choice for benign gastric ulcer is partial gastrectomy with Billroth I anastomosis. If there is any suspicion of malignancy which cannot be confirmed by frozen section, it is wiser to perform a Billroth II type of anastomosis in case later paraffin sections reveal carcinoma. The latter type of anastomosis is also preferred in cases with a very high acid output (MAO over 40 mEq/hour). The results of partial gastrectomy with Billroth I anastomosis are consistently good. The operative mortality at Groote Schuur Hospital has remained in the vicinity of 1–2% and the same applies to many other institutions. The recurrent ulceration rate is less than 1% and satisfactory results are obtained in about 95%.

In recent years pyloroplasty or gastrojejunostomy with excision of the ulcer and also vagotomy and drainage with biopsy of the ulcer has been suggested as alternative procedures. Results seem as good as those of gastrectomy have been reported by some, but others have encountered many problems. In our opinion the standard approach to benign gastric ulcer must remain distal gastrectomy with removal of the ulcer. If the ulcer is situated high up in the lesser curve an extended Pauchet manoeuvre as recommended by Tannen should be used.

**SUMMARY**

Some of the greatest advances in paediatric surgery have been in the field of paediatric gastro-enterology. Progress in some of these conditions is discussed.

**Progress in Paediatric Gastro-enterology**

S. CYWES, M.MED. (SURG.), Associate Professor of Surgery, Department of Paediatric Surgery, University of Cape Town and Principal Paediatric Surgeon, Red Cross War Memorial Children’s Hospital, Cape Town

During the last few years progress in various aspects of paediatric surgery has been phenomenal, due mainly to the acceptance of paediatric surgery as a separate specialty, and because more and more surgeons are confining themselves to the surgical problems of infants and children. This has led to a better understanding of the aetiology.
embryological development and pathophysiological processes of many anomalies and diseases, as well as advances in the pre-, intra- and postoperative management of these patients. Perhaps some of the greatest advances have been in paediatric gastro-enterology, as a tremendous amount of research has been carried out in this field.

EXOMPHALOS AND GASTROSCCHISIS

We have learnt to differentiate between these two distinct entities (see Fig. 1). In gastroscchisis the defect is alongside the umbilicus, usually to the right, and there is no covering sac as is found in an exomphalos. The mortality rate in gastroscchisis and in ruptured exomphalos has been significantly reduced by the use of Silastic sheeting reinforced with dacron, which is used to cover the defect and the protruded intestine (Figs. 2(a) and 2(b) and 3).

With daily reduction the intestine can be returned to the abdominal cavity within 7 - 10 days when a formal repair can be effected. The unruptured exomphalos is treated mainly by conservative means unless the sac is ruptured or the defect is small (under 2 cm) in diameter, producing obstructive symptoms.

The recognition and prompt treatment of hypoglycaemia in these cases have been lifesaving in many instances. A special syndrome of babies born with an exomphalos and a large tongue with episodes of hypoglycaemia has also been recognized of late (Fig. 4).

OESOPHAGEAL ATRESIA

The introduction of the Replogle tube has improved the pre-operative management of these babies. We can now afford to treat an associated pneumonia for 24 hours or
so with adequate decompression of the proximal pouch before performing definitive repair. The surgery of this lesion in all its aspects has changed over the past few years, which has resulted in a marked decrease in the mortality and morbidity of these babies, as well as improved function of the repaired oesophagus.

An extrapleural approach has made this operation safe as far as the postoperative progress and postoperative anastomotic leaks are concerned. The actual repair has been modified and we are now performing a procedure used for years on the Continent but only recently popularized by Beardmore from Montreal. In essence the fistula is ligated in continuity, the proximal oesophagus is anchored to the distal oesophagus and the repair effected end-to-side with a few 3-0 black silk sutures (Fig. 5). This procedure has reduced the number of staged procedures as it can be performed on premature infants as well. Furthermore, very little mobilization of the distal oesophagus is required with no interference with the slender vagal fibres or the tiny vessels supplying the oesophagus, resulting in hardly any inco-ordination of the oesophageal peristalsis on follow-up, as was previously encountered following a conventional end-to-end anastomosis. Similarly the well known oesophageal atresia cough is no longer heard.

Lastly, the management of patients presenting with an oesophageal atresia with no oesophagotracheal fistula has also improved. Invariably in these cases there is a long gap between the two blind ends, making a primary repair impossible. Previously the proximal pouch was exteriorized in the neck and a feeding gastrostomy was performed. At a later stage reconstruction was carried out using a segment of colon. Today we only perform the gastrostomy for feeding and leave the Replogle tube in the upper pouch. During the ensuing few months the proximal pouch (and distal oesophagus if necessary) are elongated with a mercury bougie. This is continued until the two ends of oesophagus overlap when an end-to-end repair can be effected (Fig. 6).

DUODENAL ATRESIA AND STENOSIS

The management of duodenal atresia is now well established. The use of a transanastomotic Silastic feeding tube through a gastrostomy tube has been universally adopted and has hastened the postoperative course considerably.

![Fig. 5. (a-d). Ligation of tracheo-oesophageal fistula and end-to-side anastomosis of oesophagus.](image)

**SMALL BOWEL OBSTRUCTIONS**

The aetiology and management of babies with small bowel atresias and stenoses is now standard and adopted by most. However, the method of research which culminated in the elucidation of the aetiology of this condition has opened the way for several other research projects. Foetal experimental surgery is performed in many laboratories in attempts to produce other anomalies, e.g. biliary atresias, Hirschsprung's disease and anorectal malformations.

Progress has been made in the management of babies following massive bowel resection whether as a result of multiple atresias or a volvulus. In the medical management of these babies intravenous hyperalimentation has proved itself as a most valuable aid. Concentrated feeds with high calorie content can be given by this method for weeks or months, thereby maintaining a positive nitrogen balance and actual gain in weight. This method of treatment has enabled us to persist with medical treatment without having to resort to the various surgical procedures in an attempt to delay transit time, e.g. reversal of short segments of bowel. The value of parenteral hyperalimentation was beautifully shown in one of our cases. A newborn baby weighing 1.8 kg had had a massive resection of small
bowel for multiple atretic segments, leaving him with 17 cm of small bowel. The postoperative course was uncomplicated, but soon he developed intestinal hurry and massive loss of fluids. Mouth to anus transit time was 3 - 4 minutes. With hyperalimentation and intravenous supplementation we were able to manage him for 9 months with a steady gain in weight, before he was able to maintain himself on oral diet alone. He is now 18 months and weighs 7.7 kg. The mouth to anus time is now 5 - 6 hours. Although he still has some malabsorption he does not require supplementation for excessive fluid loss.

Thus, with energetic medical management and intravenous hyperalimentation we were able to tide this baby over until the compensatory mechanisms in the remaining small bowel and large bowel could correct the massive fluid loss.

The recognition, prevention and treatment of magnesium deficiency in infants in whom the physiology of the gastrointestinal tract has been altered after surgical procedures such as resection, short circuits and fistulae are major advances. The period of risk is between 1 and 3 months of age, before the onset of mixed feeding, as the magnesium content of cow's and breast milk is relatively lower than in meat and vegetables.

The over-all management of babies with mucoviscidosis presenting with meconium ileus in the neonatal period has improved to such an extent that more and more are now surviving. Resection of the obstructed bowel with a Bishop-Koop type of ileostomy and washouts of the distal bowel with gastrografin or acetylcysteine have materially improved results. Long-term antibiotic administration, regular humidification with saline, Bisolvin and pancreatic supplementation have enabled these children to grow up relatively free from complications.

Hirschsprung's Disease

Since Hirschsprung's first description of this disease we have come a long way in the understanding and management of the condition. The clinical features, pathology and various types of definitive procedures are well known today, but the greatest progress has been in the work done to elucidate the aetiology and pathophysiology of congenital megacolon. Following some embryological studies of Okamoto and Ueda, the aetiology of aganglono-

nology is believed to be a developmental anomaly in which the transcaudal migration of neuroblasts into the alimentary tract has ceased at various stages before the twelfth week of gestation. The rectosigmoid, the most distal part for the neuroblasts to travel to, is the most common site of involvement, but the earlier the cessation of migration, the longer the segment of aganglono-

sis.

Further interesting work has been done by Ehrenpreis and his group21 in the pathophysiology of this condition. By histochemical fluorescent studies they showed that the mediation not only of parasympathetic, but also sympathetic influences to the aganglionic bowel is interrupted (Fig. 7). This functional denervation promotes spastic contraction, which is the main characteristic of the distal aganglionic segment of bowel in Hirschsprung's disease.

Recently Lawson and Nixon22 and Tobon et al.,23 have shown that manometric studies of the anal canal and rectum can be used in the diagnosis of Hirschsprung's disease. In normal subjects distension of the rectum produces relaxation of the internal sphincter and contraction of the external sphincter, whereas in patients with Hirschsprung's disease there is contraction of the internal sphincter.

ANORECTAL MALFORMATIONS

In this field progress has been made in all aspects. Firstly, unanimity on a classification of anorectal malformations was obtained in March 1970 in Melbourne by an international panel of paediatric surgeons. Secondly, preoperative radiological investigation of these babies has been shown to be of great value in making a complete diagnosis and in siting the lesion, which has enabled us to perform the correct procedure. Thirdly, the now accepted method of treatment, viz. by a definitive sacro-abdomino-perineal pull-through operation, the long-term results and continence have undoubtedly been improved, as has been shown in our series of cases.

Lastly, we are now able to assess continence not only on strict clinical criteria, but also more objectively by means of rectograms, performed by our radiological department. To complete this assessment another objective aid should be added, viz. manometric studies, which we hope to complete this year.

I have discussed the progress in some conditions in paediatric gastro-enterology. There is still a great deal to be learnt. Further improvement in management and long-term results in gastro-intestinal pathology in infants and children can only be obtained by a better understanding of normal development, and physiological as well as the pathophysiological processes.

Some Current Views on Pancreatitis

SUMMARY

Current views on the pathogenesis, classification, diagnostic criteria, natural history and surgical treatment of pancreatitis are reviewed.

The past decade has seen few dramatic advances in the diagnosis and treatment of pancreatitis. The aetiological pathogenesis remains uncertain, the diagnosis is still difficult and the management is seldom straightforward. But there has been a broadening in the understanding of the classification, diagnostic features, natural history and surgical management of the disease.

PATHOGENESIS

The cause of acute pancreatitis remains elusive, and the aetiology and pathogenesis of the disease is almost as controversial now as it was some 50 years ago.

McCUTCHEON, in an attempt to unify the various aetiopathological factors, has reviewed the evidence for reflux of duodenal contents into the pancreatic duct as the mechanism responsible for initiating the disease and concludes that reflux pancreatitis is the common denominator in all cases of pancreatitis. This would appear to be an over-simplification of the problem, particularly in alcohol-induced pancreatitis, since many patients do not give a history of nausea or vomiting before the onset of pain. Furthermore, the elegant experimental studies of DAVIS suggest that alcohol-induced pancreatitis is due to factors other than duodenal reflux into the pancreatic duct.

The pathological changes in acute pancreatitis range from slight oedema to extensive haemorrhagic infarction. A vicious circle of increasing vascular damage occurs in acute pancreatitis, and experimental studies by GOODHEAD support the view that these changes in pancreatic blood flow are crucial in determining the outcome of an attack. A decreased blood flow favours the development of acute haemorrhagic pancreatitis. Low-molecular-weight dextran has been shown to exert a protective effect in maintaining a normal perfusion rate and has been used, with good results, in patients with severe acute pancreatitis. Another aspect of the pathogenesis which has a therapeutic bearing has recently been reviewed by CREUTZFELD AND SCHMIDT.

These workers have stressed that the morphology of pancreatitis may be best explained by the intrapancreatic effect of phospholipase A and elastase, and that only small amounts of trypsin are required for activation of these enzymes. It will be interesting to note whether this de-emphasis of the dominant role of trypsin in the pathogenesis of pancreatitis will herald a decline in the vogue of the antitryptic preparation Trasylol in this disease.

A challenging breakthrough in the pathogenesis of alcohol-induced pancreatitis has recently been made by SARLES et al. These workers were able to reproduce the histological lesions of calcific pancreatitis in man by means of a two-year period of ethanol intoxication in the rat. The changes in the affected lobules in the experimental animal comprised protein plugs, some of which were calcified, in the ducts; acinar cell replacement by dilated ducts; and sclerosis. SARLES et al. believe that the primary disturbance in calcific pancreatitis is protein precipitation in the ducts leading to duct obstruction and, subsequently, to duct dilatation, acinar cell atrophy and fibrosis.

CLASSIFICATION

The conventional clinical classification has given way to the aetiological and, more recently, the clinico-pathological classification.

The aetiological approach has the great advantage of affording an insight into the natural history of the disease and of providing a guide as to the advisability or surgery in a particular patient. Alcohol-induced pancreatitis account for 62% of pancreatitis in the Cape Peninsula, and biliary disease, miscellaneous and unknown causes for the remainder.

The clinico-pathological classification recognizes acute, acute relapsing, chronic relapsing and chronic varieties. In the acute varieties, clinical and pathological restitution takes place following the attack, whereas the chronic varieties show permanent residual pancreatic damage. The main shortcoming of this classification is that it is largely dependent on histological confirmation, a problem in centres such as ours where laparotomy is not readily undertaken and where pancreatic biopsy is viewed with disfavour. Furthermore, the clinico-pathological classification is a pathological rather than a clinical classification and does not allow separation of those patients in the chronic groups...
