Dilated cardiomyopathy (DCM) is defined by the presence of left ventricular systolic dysfunction and dilatation in the absence of abnormal loading conditions (e.g. hypertension or valve disease) or coronary artery disease sufficient to cause global systolic impairment. Right ventricular dilation and dysfunction may be present, but are not necessary for the diagnosis. DCM is an important cause of heart failure, and a common indication for heart transplantation. Studies from Europe and North America suggest that 20 - 50% of patients with dilated cardiomyopathy (DCM) may have familial disease. There is little information on the frequency and clinical genetics of familial DCM in Africa.

**Background.** Studies from Europe and North America suggest that 20 - 50% of patients with dilated cardiomyopathy (DCM) may have familial disease. There is little information on the frequency and clinical genetics of familial DCM in Africa.

**Purpose.** To determine the frequency and probable mode of inheritance of familial DCM in patients referred for investigation of the cause of DCM at a tertiary centre in Cape Town.

**Methods.** We conducted a retrospective analysis of consecutive patients diagnosed with DCM between 1 February 1996 and 31 December 2009 to determine the frequency of familial disease.

**Results.** Of 109 unrelated patients with DCM, 29 (26.6%) had familial disease. Their mean age of onset of cardiomyopathy (28.01 (standard deviation (SD) 15.33) years) was significantly younger than that for non-familial cases (39.1 (SD 12.6) years) (p=0.001). Male predominance (N=21, 72.4%) and racial distribution (15 (48.3%) coloured patients, 10 (34.5%) black Africans, 4 (13.8%) white individuals, and 1 (3.4%) of Indian descent) of familial DCM probands were similar to the non-familial cases. Of the 29 patients with familial DCM, 2 (7%) had at least one relative diagnosed with peripartum cardiomyopathy. Pedigree analysis of the 29 families was consistent with autosomal dominant inheritance in 72.4%, autosomal recessive inheritance in 17.2% and X-linked recessive inheritance in 10.4%.

**Conclusions.** Familial DCM affects at least a quarter of African patients with DCM, presents at a young age, is associated with peripartum cardiomyopathy, and follows an autosomal dominant pattern of inheritance in the majority of families. Family screening for familial DCM is indicated in all cases of unexplained DCM, including patients with peripartum cardiomyopathy.

**Methods**

**Study design**

This was a retrospective hospital-based study of the frequency and clinical genetics of familial DCM in a cohort of DCM patients referred to the cardiomyopathy clinic in the GSH Cardiac Clinic. The frequency of familial DCM was based on a detailed family history in all individuals and family screening of first-degree relatives of probands with a positive history for confirmation of familial disease. Familial DCM was defined as the presence of DCM in at least one first-degree relative of the proband and/or sudden unexplained death under the age of 35 years in a first-degree relative.

**Study population**

We reviewed the medical records of all patients evaluated for a cause of cardiomyopathy from 1 February 1996 to 31 December 2009. These patients were seen in a dedicated cardiomyopathy clinic, where one of the authors (BMM) has a special interest in disorders of heart muscle, and do not reflect the total experience of the GSH Cardiac Clinic. Patients included were those with DCM, as evidenced by clinical signs and symptoms of heart failure associated with left ventricular dilatation and a left ventricular ejection fraction less than 35%.
Clinical genetics
A two- to five-generation family pedigree was constructed for every patient with DCM. If a subject with DCM had any first-degree relative who was also affected with DCM, those first-degree relatives were invited for screening for DCM by history, physical examination, electrocardiogram (ECG), echocardiography and cardiac catheterisation where indicated. For deceased relatives, medical records were reviewed when available. Relatives with other cardiac disorders that could account for left ventricular dysfunction were excluded. Pedigree analysis was performed for all affected families to ascertain the probable pattern of inheritance of familial DCM. Pedigrees were constructed using the Cyrillic 2.1 software programme (http://www.cyrillicsoftware.com/).

Statistical analysis
Results of quantitative variables are given as mean (standard deviation (SD)). Categorical variables are represented as number and percentage. Pearson’s chi-square or Fisher’s exact test was used to compare the relative frequency of characteristics between individuals. All p-values are two-sided, and p-values < 0.05 are considered to indicate statistical significance.

Ethical considerations
The study was approved by the University of Cape Town Faculty of Health Sciences Human Research Ethics Committee (REC Ref. No. 197/96). Participants gave written informed consent. All eligible patients were asked for permission to invite their first-degree relatives (parents, siblings and children) to participate.

Results
Frequency of familial DCM
Of 109 unrelated cases with DCM studied, 29 (26.6%) had familial DCM. They were derived from all the populations of Cape Town and reflected the referral base of GSH, with 15 (48.3%) coloured/Indian descent, 10 (34.5%) black African, 4 (13.8%) white, and 1 (3.4%) of Indian descent. A total of 40 individuals with familial DCM were finally identified through family screening of the 29 original unrelated patients.

Characteristics of patients with familial DCM
The 29 unrelated cases with familial DCM had a mean age at diagnosis of 28.01 (SD 15.3) years, with a preponderance of males (N=21, 72.4%); their characteristics were comparable to the total of 40 individuals with familial DCM from the 29 families studied (i.e. 72.5% of them were male, with a mean age at the time of diagnosis of familial DCM of 25.58 (SD 15.1) years). The age of the individuals with familial DCM was significantly lower than that of patients with non-familial DCM, who had a mean age of 39.1 (SD 12.6) years at the time of diagnosis (p=0.001) (Table I).

There was no difference in degree of effort intolerance measured by New York Heart Association functional class at presentation between the index cases with familial and non-familial DCM (Table I). The patients with familial and non-familial DCM also had similar heart rates and mean systolic blood pressures at presentation (i.e. 95.6 (SD 23.3) vs. 94.9 (SD 19.5) beats/min (p=0.496) and 100.1 (SD 14.9) v. 101.8 (SD 18.1) mmHg (p=0.397), respectively). While the frequency of ECG left bundle-branch block was lower in the familial cases (17.2%) compared with the non-familial cases (36.3%), the difference was not statistically significant (p=0.123). However, patients with familial DCM had significantly less ventricular dilation than the non-familial cases, i.e., ventricular end-diastolic dimension (LVEDD) being 6.2 (SD 1.1) cm in the familial group versus 6.8 (SD 1.4) cm in the non-familial group (p=0.001) (Table I).

Clinical genetics of familial DCM
Table II summarises the pedigree analysis of the families with DCM that were studied. Pedigree analysis of the 29 families was consistent with AD inheritance in 21 families (72.4%). An autosomal recessive (AR) inheritance pattern was observed in 5 families (17.2%). X-linked recessive (X-LR) inheritance was seen in 3 (10.4%) of the familial DCM families. The examples of family pedigrees with AD, AR, and X-LR inheritance are depicted in Fig. 1, and the full list of pedigrees is available online at http://www.medicine.uct.ac.za/Supplementary%20File%20-%20Figure%202.DOC.

The number of affected first-degree relatives per family was 2.16 (SD 1.14). In these 29 families with DCM, the number of first-degree relatives at risk was 3.45 (SD 2.23) per family. One family (3.4%) had a clear history of a member with sudden cardiac death before the age of 35 years. Of the 29 families included in the analysis, 9 (31.0%) had second-degree relatives who were affected.

It is noteworthy that 2 of the 29 unrelated patients (7%) with familial DCM had at least one relative diagnosed with peripartum cardiomyopathy, confirming that some cases of peripartum cardiomyopathy are part of the spectrum of familial DCM.

Discussion
The first familial cases of cardiomyopathy were reported in 1949; subsequently there have been many publications on familial DCM. This study extends the observations made in Western populations to Africa. We show that familial DCM occurs in 26.6% of cases of DCM and is a disease of young males with an AD pattern of inheritance in the majority of families. We also confirm that some cases of peripartum cardiomyopathy, which occurred in the context of familial DCM in 2 families, are part of the spectrum of familial DCM.

Our finding of familial disease in a quarter of DCM patients is in line with the findings of others, who have found inherited disease to constitute 20 - 50% of DCM. A prospective echocardiographic study that screened first-degree relatives of patients with DCM estimated the rate of familial DCM to be 20.3%, as 315 relatives of 59 index patients with DCM underwent screening with echocardiography, including coronary angiography for those older than 40 years in order to exclude coronary artery disease. DCM was found in 18 relatives (20% of index patients), whereas only 5% had been suspected of having familial disease on the basis of family history alone. In another prospective study of 56 probands with DCM, the definite familial DCM rate was estimated at 25%, where the diagnosis of familial disease was based on first-degree relatives...

DCM = dilated cardiomyopathy; SCD = sudden cardiac death under the age of 35 years.

With a diagnosis of DCM on cardiac catheterisation or autopsy, or a first-degree relative with both an echocardiographic LVEDD greater than two SD above the mean and a left ventricular ejection fraction (LVEF) below 50%,19 when left ventricular enlargement was taken as a clinical indicator of DCM, two other studies found the frequency of familial DCM to range from 35%20 to 48%.21

Over 70% of our patients with familial DCM were male. This male preponderance in DCM has been described previously.22,23 In hospital-based studies in sub-Saharan Africa, DCM occurs twice as commonly in men as in women.24 A study of 637 DCM patients, including 130 patients with familial DCM, found that male patients constitute approximately 70% of both non-familial and familial DCM cohorts studied.25

The finding of a younger age of onset of familial DCM compared with non-familial disease is also consistent with other studies and compatible with a genetic cause.25 An earlier systematic study of familial DCM also found it to occur at a younger age (mean age of onset 32 years) compared with patients with idiopathic DCM.26 Another study comparing familial and non-familial DCM found that only a younger age of onset was predictive of familial disease; no other clinical or morphological features were useful in distinguishing the two entities from each other.27 Likewise, Grünig et al. found that 156 of 445 DCM patients confirmed to have familial DCM were much younger than those without familial disease.28 Early-onset cardiovascular disease is likely to be influenced by genetic factors more than late-onset disease.28

We found that at least 70% of familial DCM families demonstrated an AD pattern of inheritance, an observation supported by many
previous publications. Familial DCM has been reported most commonly with AD inheritance in up to 90% of cases.\textsuperscript{8,27,29} The genetic and clinical heterogeneity observed is in keeping with causation by multiple genes, with gene-environment interactions altering expression of disease.\textsuperscript{27} To date, over 25 mutations have been described in autosomal genes that cause familial DCM.\textsuperscript{8,29} Some of the commonly mutated genes causing the AD type of familial DCM include lamin A/C, beta-myosin heavy chain, alpha-myosin heavy chain, actin, alpha-actinin-2, metavinculin, desmin, sarcoglycan, troponin T, alpha-tropomyosin, titin and phospholamban.\textsuperscript{4} There are also genetic polymorphisms that are associated with an increased risk of developing DCM in some populations.\textsuperscript{30,31}

An AR pattern of inheritance may account for up to 10% of familial DCM, and is commoner in certain ethnic groups and in cases of infantile DCM.\textsuperscript{32} Unlike many other studies, we found a slightly higher rate of AR inheritance, 17.2%. A mutation in cardiac troponin I has been shown to cause AR DCM in one family.\textsuperscript{33} X-linked familial DCM has been reported in 5 - 10% of cases.\textsuperscript{23} X-linked types of familial DCM usually result from mutations in the dystrophin gene, which are commonly associated with skeletal muscle weakness and elevated levels of creatinine kinase.\textsuperscript{8,34,35} In some cases, DCM has been the only presenting feature of patients with Becker muscular dystrophy or in female carriers.\textsuperscript{36} Furthermore, Becker muscular dystrophy and DCM have been seen in the same family, suggesting that it may be difficult to draw conclusions about phenotype from genotype.\textsuperscript{37,38} The determination of inheritance patterns by clinical genetic analysis of familial DCM is not straightforward. Use of family history and construction of a three- or four-generation family pedigree may not be sensitive enough when used

Fig. 1. Pedigrees and mode of inheritance. Pedigree analysis of the 29 families was consistent with autosomal dominant inheritance (e.g. panel A) in 72.4\% (N=21), autosomal recessive inheritance (e.g. panel B) in 17.2\% (N=5) and X-linked recessive inheritance (e.g. panel C) in 10.4\% (N=3). Filled symbol = phenotypically affected subject; empty symbol = unaffected subject; circle = woman, square = man; diamond = gender unknown; arrow = proband; bar crossing the symbol = deceased. All the pedigrees are available as supplementary material online at http://www.medicine.uct.ac.za/
We also acknowledge the expert assistance of Ms Lebogang Montewa, those with peripartum cardiomyopathy), in whom family screening of inheritance. These findings have major implications for the clinical years. Over 70% of the affected families demonstrated an AD pattern and an early age of onset, with the mean age at diagnosis being 28 with unexplained DCM, occurring in a quarter of DCM patients are not sufficiently specific for familial DCM.13 Furthermore, familial ORIGINAL ARTICLES likelihood of finding a responsible gene mutation when molecular genetic testing is properly applied.15,16 In contrast, the identification of pathogenic mutations in familial DCM is more challenging because of extreme genetic heterogeneity. Nevertheless, the clinical screening of families at risk for an inherited form of cardiomyopathy leads to earlier identification, earlier treatment, and improved outcomes with or without molecular genetic testing.20,25 This study has the limitations of a retrospective design. Because it was conducted in a tertiary referral centre for inherited cardiomyopathies there may be a referral bias, which may overestimate the true frequency of familial DCM. On the other hand, the number of familial DCM cases in our cohort may have been underestimated for several reasons. First, a varying spectrum of cardiac abnormalities may be present in asymptomatic relatives of patients with familial DCM. Hence, familial and sporadic types of the disease are not easily distinguishable by family history and clinical screening of first-degree relatives in the absence of a ‘gold standard’ for diagnosis. Second, our diagnosis of familial DCM was based on family history; and screening of first-degree relatives of individuals with a positive family history to confirm the presence of familial DCM. It is therefore likely that we report the minimum frequency of familial DCM, and that the screening of the individuals without a family history is likely to yield a higher prevalence of familial disease.26

Conclusion We have shown that familial DCM is common in African patients with unexplained DCM, occurring in a quarter of DCM patients studied. We found that familial DCM has a predilection for males and an early age of onset, with the mean age at diagnosis being 28 years. Over 70% of the affected families demonstrated an AD pattern of inheritance. These findings have major implications for the clinical evaluation of patients with unexplained cardiomyopathy (including those with peripartum cardiomyopathy), in whom family screening of first-degree relatives for cardiomyopathy is indicated. We are grateful to the patients and families who participated in this study. We also acknowledge the expert assistance of Ms Lebogang Montewa, Ms Stella du Toit, Mr Simpiwe Nkepu, Ms Carolina Lemmer, and Sisters Maitele Tshifulo, Unita September and Veronica Francis in the execution of this study. We have no conflicts of interest to declare. The authors are funded in part by research grants from the University of Cape Town, the Medical Research Council of South Africa, the Discovery Foundation, the National Research Foundation of South Africa, and the Lily & Ernst Haußmann Research Trust.
