Southern African clinoptilolite capability as an ion-exchanger with respect to Cu$^{2+}$ and Co$^{2+}$ was investigated in order to consider its possible application at removing metals from aqueous solutions. The column method was used in the cation-exchange processes with synthetic solution concentrations of 0.07 M (3.86 g/l), 0.33 M (19.31 g/l) and 0.66 M (38.63 g/l) of Cu$^{2+}$ solution and 0.07 M (3.34 g/l), 0.33 M (16.69 g/l) and 0.66 M (33.37 g/l) of Co$^{2+}$ solution. Synthetic non-mixed sulphate solutions of copper and cobalt recorded maximum cation uptakes of 79% and 63% with 0.02 M HCl-activated clinoptilolite respectively. From the Cu/Co mixed solutions, both cobalt and copper recorded a 79% uptake with 0.02 M HCl-activation. The 0.04 M HCl activation gave percentage removals of 79% and 77% for Co$^{2+}$ and Cu$^{2+}$ respectively. In the ion-exchange evaluation part of the study, it was found that in every concentration range, the adsorption mass ratio of clinoptilolite to metalation was found in the Langmuir equation. It was found that the adsorption process depends on the hydrated radius of the cation being exchanged, the concentration of the acid that activates the clinoptilolite and the concentration of the targeted cation in solution.

Introduction

Water pollutants emanating from metallurgical operations have been highlighted as one of the avenues by which groundwater can be polluted thus threatening valuable water sources. The need for clean drinking water is vital for the promotion of good health and with it comes the challenge to provide safe and high-quality drinking water. Groundwater is one of the major sources of drinking water in South Africa. These freshwater sources are faced with the challenge of deteriorating quality due to the prevalence of pollution. The need for removal of metal species in water and the general purification of these waters cannot be over emphasised. A number of purification methods are currently employed in the water purification industry and these include ion exchange, ultrafiltration, phytoextraction, electrodialysis and reverse osmosis (Geselbracht, 1996; Schnoor, 1997). However, industrial wastewaters often contain a cuisine of metals that may impose cost implications when it comes to purification.

Among the water purification technologies, ion exchange is most commonly employed in industrial water treatment (Inglezakis et al., 2005). The ion-exchange reaction occurs between two or more phases, one of which is liquid (solution or melt), whereby an exchange occurs of two or more ions that are more or less strongly bound to each phase. The ion exchanger may be a resin, activated carbon, a zeolite or clay mineral. Zeolites, synthetic or natural, are aluminosilicates that have a framework structure with enclosed cavities and tunnels which are occupied by freely moving hydrated cations that make ion exchange possible.

Clinoptilolite is the most abundant and cosmopolitan zeolite (Inglezakis et al., 2005) and it has been widely exploited for its ion-exchange capabilities since it can easily exchange its interstitial sodium for external cations in solution (Kuronen et al., 2006). Natural zeolites often do not perform optimally as required for industrial applications. Therefore, chemical conditioning of zeolites to improve their performance is often carried out. This conditioning removes certain cations from zeolites that may hinder ion exchange and expose the easily exchangeable ones. It has been previously reported in the literature (Zamzow et al., 1992) that sodium-type natural clinoptilolite favours the exchange of Cu$^{2+}$ over Co$^{2+}$. Cation-exchange isotherms of Cu$^{2+}$ exchange on chabazite and clinoptilolite (Semmens and Seifarth, 1978; Blanchard et al., 1984; Assenov et al., 1988), Co$^{2+}$ exchange on clinoptilolite (Blanchard et al., 1984), Zn-exchange on clinoptilolite (Semmens and Seifarth 1978; Blanchard et al., 1984; Assenov et al. 1988) and Cr$^{6+}$ exchange on phillipsite and chabazite (Pansini et al., 1991) are also reported in literature.

Herein, we report on the ability of the South African natural and modified clinoptilolite at removing heavy metals such as Cu and Co from their synthetic solution using the ion-exchange capability of the zeolite. The effect of concentration of the aqueous solutions and the degree of HCl activation of the clinoptilolite in its removal efficiency of the clinoptilolite were also studied.

Experiments

Zeolite source, characterisation and conditioning

The natural clinoptilolite used in this study was sourced from the Vulture Creek, KwaZulu-Natal Province of South Africa. In preparation for mineralogical studies and characterisation, the
Solutions of Cu and Co were prepared by dissolving CoSO$_4\cdot7$H$_2$O and CuSO$_4\cdot5$H$_2$O in deionised water at pH 6.5. The non-mixed Cu$^2+$ and Co$^{3+}$ aqueous solutions of concentrations 0.0020 M, 0.0698 M and 0.2000 M which corresponded to 0.032 g, 1.109 g and 3.177 g of Cu$^2+$ and 0.030 g, 1.028 g and 2.947 g of Co$^{3+}$ were prepared by dissolving CoSO$_4\cdot7$H$_2$O and CuSO$_4\cdot5$H$_2$O salts in deionised water in 250 mL volumetric flasks.

Studies on the mixed solutions of copper and cobalt were done with solutions of Cu and Co prepared at stoichiometric ratios of Co:Cu – 1:1, 1:5, 1:9, 5:1 and 9:1 which corresponded to these concentrations of Co:Cu – 0.0020:0.0020 g/L, 0.0020:0.0698 g/L, 0.0020:0.2000 g/L, 0.0698:0.0020 g/L and 0.2000:0.0020 g/L respectively. Studies on the Co/Cu mixed synthetic solutions were done with solutions of copper and cobalt prepared at stoichiometric ratios of Co:Cu – 1:1, 1:5, 1:9, 5:1 and 9:1 which corresponded to these concentrations of Co:Cu – 0.0020:0.0020 g/L, 0.0020:0.0698 g/L, 0.0020:0.2000 g/L, 0.0698:0.0020 g/L and 0.2000:0.0020 g/L respectively. These solutions were assayed using atomic absorption spectroscopy (AAS), (model Varian Spectra 20/20).

**Batch adsorption studies on synthetic solutions**

The Cu and Co ion-exchange processes on the clinoptilolite were conducted at room temperature. Glass columns of 2 cm diameter and 30 cm of length were pre-loaded with 25 g of either natural clinoptilolite (as received) or HCl-activated clinoptilolite. Aliquots of 25 mL of the prepared Cu- and Co-bearing solutions of desired concentrations were passed through each of the two types of zeolites. These were afforded the same solution-zeolite contact time. After passing through the zeolite-packed column the resultant solutions were assayed using atomic absorption spectroscopy (AAS) in order to ascertain the zeolite’s removal efficiency. The flame type used was air-acetylene and the adsorption wavelengths for the two metals were Cu (324.7 nm) and Co (240.7 nm). Standards of 1 000 (mg/ℓ), 2 000 (mg/ℓ) and 3 000 (mg/ℓ) were then prepared and a calibration curve was drawn using these standards. Dilution was applied stoichiometrically where the concentrations of the unknown solutions of copper and cobalt exceeded the standards’ concentration range of the standards.

The metal-removal percentage from the solutions and distribution ratio were calculated as follows:

\[
\% \text{ Uptake} = \frac{C_o - C_f}{C_o} \times 100, \tag{1}
\]

where:

Co and Cf are the initial and final metal concentrations, respectively.

**Results and discussion**

**Clinoptilolite characterisation**

Results of the X-ray fluorescence (XRF) analysis are presented in Table 1. This characterisation showed that clinoptilolite contained exchangeable ions of sodium, potassium, calcium and magnesium. This zeolite has an Si/Al ratio of 5.96 (mol/mol) and the corresponding ratio of (Na + K)/Ca was 3.4. XRF also confirmed that the zeolite was a high silica clinoptilolite enriched with Mg, K and Na. The XRD plot in Fig. 1 shows a typical mineralogical diffraction pattern of a crystallite with a composition of 70% SiO$_2$, 12% Al$_2$O$_3$, 2% Na$_2$O, 5% K$_2$O, 2% CaO and 2.5% Fe$_2$O$_3$.

**Metal removal from synthetic solutions**

The ion-exchange kinetics of Co$^{3+}$ and Cu$^{2+}$ as a function of their concentrations in their respective solutions were studied at room temperature by varying their concentrations with time and keeping all other parameters constant. From the results shown in Figs. 2 and 3, it can be confirmed that the percentage metal removal decreased with an increase in metal concentration in the aqueous solutions. This may be due to the fact that particles always diffuse faster when they are less packed, thus they move faster in dilute solutions and more slowly in concentrated solutions.

**Metal removal from the double-component systems**

The copper/cobalt mixed solutions exhibited results similar to
the single-salt solutions in the sense that the removal efficiency was high with dilute solutions than it was with concentrated solutions and the results shown in Figs. 4 to 7 confirm this assertion. High uptakes ranging between 70 to 79% were recorded with both Cu and Co removal in the concentration ratios of 0.07:0.07 M.

In solutions where there was more cobalt than copper in terms of the ratio (Co:Cu = 9:1 and 5:1) there seemed to be difficulty in removing either of the metals using the 0.04 M HCl-activated clinoptilolite. Co removal efficiency in Co:Cu = 9:1 solutions using 0.02 M HCl was 62% and was reduced to 48% when 0.04 M HCl-activated clinoptilolite was used while a ratio of Co:Cu = 5:1 showed a decrease in removal efficiency from 64% using 0.02 M HCl-activated clinoptilolite to 57% when 0.04 M HCl-activated clinoptilolite was used. On the other hand, Cu removal from the Co:Cu = 9:1 ratio showed a removal efficiency decrease from 59% when 0.02 M HCl was used to 55% when 0.04 M HCl-activated clinoptilolite was
used. It is possible that there is an intermediate complex that is formed between Co\(^{2+}\), Cu\(^{2+}\) and water molecules that is too bulky to favour fast removal of these metals from the aqueous solution. The presence of Cu\(^{2+}\) in high concentrations (Co:Cu = 1:9 and 1:5) in the double-component solution favours the removal of both Co and Cu. This somehow contradicts the notion that less concentrated metal solutions favour fast removal of that specific metal than concentrated solutions. However, the fact that the highest removal efficiencies with these solutions are recorded with the more dilute solutions agrees with the notion.

**Langmuir and Freundlich adsorption isotherms**

The sorption data was subjected to Langmuir and Freundlich adsorption isotherms. The equilibrium data for single metal solutions was correlated with the Langmuir isotherm according the following equation (Langmuir, 1918):

\[
x/m = \frac{(abCr)}{(1+bCr)}
\]

where:

- \(x/m\) is the number of metal ions adsorbed onto the clinoptilolite
- \(a\) and \(b\) are Langmuir constants related to adsorption capacity and adsorption energy, respectively. Constant \(a\) is the maximum sorption capacity and represents single layer coverage of the adsorbent (clinoptilolite) in contact with the adsorbate (metal solution). The variable \(b\) represents enthalpy of adsorption and changes with temperature. Application of the Langmuir Model to the data is shown in Figs. 8 to 11.

The Langmuir equation can be rearranged in a linear equation form and rewritten as follows:

\[
\frac{C_r}{(x/m)} = \frac{1}{ab} + \frac{1}{a} \cdot C_r
\]

To make the Langmuir plots, \(\frac{C_r}{(x/m)}\) is plotted against \(C_r\) and a straight-line graph was obtained for this plot. The data of the non-mixed salt solutions fit the Langmuir Model very well with \(R^2\) values > 0.9 for the dilute sulphate solutions of both Cu and Co. According to the Langmuir Model and \(R^2\) correlation values, Cu\(^{2+}\) uptake is more favoured than Co\(^{2+}\). The ion-exchange capacity of Cu\(^{2+}\) and Co\(^{2+}\) indicates that clinoptilolite favours Cu\(^{2+}\) over Co\(^{2+}\) ions. In solution, these ions are present in aqua-ionic forms and Cu\(^{2+}\) is found in a tetra-aqua
form while Co\(^{2+}\) is exists in the hexa-aqua form. This suggests that Cu\(^{2+}\) is surrounded by four molecules of water while Co\(^{2+}\) is surrounded by six. These hydrated ions pass through the clinoptilolite (Jama and Yucell, 1990) and although the charges of the ions are the same, they have different hydrated radii – Cu\(^{2+}\) has a lower hydrated radius than Co\(^{2+}\). The adsorption of a metal ion by an ion-exchanger largely depends on its hydrated radius. The larger the diameter the slower its mobility and the less likely its exchange would occur (Erdem et al., 2004). It appears that for easy ion exchange some of the water molecules surrounding the cation must be lost in order to initiate the ion-exchange process. The Langmuir Model effectively describes the adsorption data obtained in these experiments with all values of R\(^2\) being greater than 0.99 for the dilute solutions of 0.07 M metal sulphate being exchanged with 0.02 M HCl-activated clinoptilolite. The isotherms also confirmed the selectivity of clinoptilolite as being more favourable for Cu\(^{2+}\) than Co\(^{2+}\). The clinoptilolite was observed to generally have good selectivity for both cations. This could be attributed to the high Si/Al ratio of clinoptilolite with a low ionic field that results in good selectivity.

Another mathematical model used to fit the data obtained in this study was the Freundlich isotherm (Altin et al., 1998). This model is known for its good fit of data over a wide range of concentrations. It gives an equation that includes the heterogeneity of the surface of the ion exchanger and the exponential distribution of active sites and their energies. The Freundlich equation is given by:

\[
\log C_{\text{ads}} = \log K + \frac{1}{n} \log C_{\text{eq}}
\]

where:
- \(C_{\text{ads}}\) is the equilibrium concentration in ppm
- \(C_{\text{eq}}\) is the number of metal ions adsorbed onto the clinoptilolite
- \(K\) is related to temperature
- \(n\) is a characteristic constant for any system under study

It was observed that the data followed the Freundlich Model as well. The R\(^2\) values were generally higher than 0.95.

The selectivity of a zeolite for one ion over another in a matrix is a result of physicochemical and stereochemical factors. These are hydrated radii, the hydration enthalpy of the cation and the space requirements in the micropores of clinoptilolite (Inglezakis et al., 2005). Every metal in solution possesses a hydrated layer which has a characteristic thickness and degree of stability. It has been proven that ions with large radii often show large rejections while smaller ions are often favoured by exchangers (Tansel et al., 2006). Cu\(^{2+}\) is a smaller ion with a

smaller hydrated radius than Co$^{2+}$ and therefore Cu$^{2+}$ is highly favoured for removal by clinoptilolite within the parameters of this study.

It is also known that the hydration enthalpy of Cu$^{2+}$ is low due to the number of water molecules solvating it (Carrillo-Tripp et al., 2006). The easy removal of Cu compared to Co can be attributed to the geometry of the hydrated copper ion (Inglezakis et al., 2005). Cu$^{2+}$ forms a square-planar complex in water, [Cu(H$_2$O)$_4$]$^{2+}$, while Co$^{2+}$ forms a tetrahedral aqua-complex, [Co(H$_2$O)$_6$]$^{2+}$ due to its hexavalent ion. The square planar complex is less bulky and therefore migrates easily in solution compared to the bulky tetrahedral aqua-complex.

The strength of the exchange sites on the zeolite also affects the exchange rate. Natural clinoptilolite is weakly acidic hence the rate of ion exchange in clinoptilolite is expected to be high. This is even more so with the acid-activated clinoptilolite.

**Effect of solution concentration**

In general, natural clinoptilolite appeared to remove the metals more efficiently from dilute solutions than from concentrated ones. Athanasiadis and Helmreich (2004) reported that high metal-solution concentrations showed low ion-exchange rates compared to low concentrations. These researchers concluded that this was due to the high concentration of the counter ion in the solution which was generally true for all the analytes. However, an outlier was observed with Co removal from the Co mixed solutions using 0.04 M HCl-activated clinoptilolite (Fig. 6). This must have been due to an unevenly mixed size proportion of the zeolite used. It is possible that more of the smaller size range of particles was present in this batch. Small particle size increases the exchange efficiency due to surface area: volume ratio. The cation being exchanged moves a shorter distance in smaller grains than in larger ones thus speeding the exchange rate.

**Effect of HCl conditioning**

The BET analysis shows no significant changes in pore volume with increase in HCl activation concentration of the zeolites. Analyses of original, 0.02 M, 0.04 M and 0.10 M HCl-activated clinoptilolite revealed that there is a decrease pore volume and surface area as the HCl concentration increases. The results of pore volume measurements are shown in Table 3.

The SEM image in Fig. 16 shows a more open structure of the HCl-activated clinoptilolite’s surface compared to the inactivated zeolite in Fig. 17. This could explain why acid-activated clinoptilolite performed better than the original zeolite. There were some morphological changes brought about by acid activation on clinoptilolite structure when comparing the two SEM images.

The FTIR spectra in Fig. 18 give a clear picture about the effect of chemical conditioning. Acid treatment is said to remove the non-zeolitic components thus increasing the concentration of zeolite minerals. Elimination of this material requires more complex procedures (Vanloorn and Duffy, 2000; Al-Degs et al., 2004). Infrared techniques have been used by previous researchers for the identification of soil and clay minerals (Gadsden, 1975). Figure 18 depicts the FTIR-spectra of the original and acid-treated forms of the clinoptilolite used in this study.

The results obtained from FTIR spectroscopy agree with the observations made with respect to the performance of the
clinoptilolite where 0.02 M HCl-activated zeolite was the best ion-exchanger, i.e. higher percentage extractions were obtained with this form of zeolite than those obtained with original and 0.04 M HCl activation concentration. Over the range of 4 000 and 3 600 cm⁻¹ the original and 0.04 M HCl-activated forms of clinoptilolite showed no peaks while the 0.02 M HCl-activated form showed peaks. Peaks observed at this range are typical of water absorption (Majedova, 2003; Al-Degea et al., 2004). This shows that water adsorption and retention by clinoptilolite is increased by HCl activation at 0.02 M concentration and can be used to explain the good performance of this form of activated clinoptilolite in ion exchange compared to the other 2 forms (original and 0.04 M HCl-activated forms). Over the range of 2 500 and 2 000 cm⁻¹, the 0.02 M HCl-activated clinoptilolite showed 2 intensive peaks and yet again the original and the 0.04 M HCl-activated forms showed none. This could be a result of 0.02 M HCl activation washing out the non-zeolitic impurities present in the original form as confirmed by XRD, XRF and SEM-EDS (Gadsden, 1975). The disappearance of these peaks with the 0.04 M HCl-activated form could be due to the strength of the acid resulting in the destruction of the active sites observed with the 0.02 M HCl-activated clinoptilolite. There were broad peaks observed for all the clinoptilolite forms at 1 558 cm⁻¹ which may be due to the bending vibrations of adsorbed water. This is expected since given its porous structure, desiccation of the zeolite at high temperatures 50°C will increase its water absorption properties (Ng and Mintova, 2008). Zeolites that have K⁺ in high amounts have low water-adsorption capacity (Hunger et al. 1999; Kirchhock et al. 2000). This could probably explain why the original clinoptilolite does not show these peaks. It is also possible that the K⁺ in the acid activated zeolite was leached out by the acid, thus increasing their water sorption capacity.

The identification of peaks between 1 500 and 1 000 cm⁻¹ FTIR indicates the presence of a high content of calcite in the sample as confirmed by SEM-EDS. The strong band at 1 341 cm⁻¹ (due to Si-O stretching) is the main characteristic band for quartz (Al-Degea et al., 2004). The peaks observed between 1 000 and 600 cm⁻¹ are present in all the forms of clinoptilolite, one characteristic band appears at 836 cm⁻¹ for all the forms. This is the quartz band (Al-Degea et al., 2004). The peak that appears at 753 cm⁻¹ for the original form of clinoptilolite appears at 759 cm⁻¹ for the activated zeolite. There is a peak that appears at 686 cm⁻¹ for the original form while for the acid-activated form it appears at 635 cm⁻¹. This shift could be attributed to the action of the acid.

In the non-mixed salt solutions, activated clinoptilolite generally performed better at taking up metal than the original zeolite. The original clinoptilolite showed capacity to remove 37% Cu and 39% Co. Uptakes of 79% and 63% for Cu²⁺ and Co²⁺ were recorded with 0.02 M and 0.04M HCl activation, respectively. In the mixed solutions, both cobalt and copper recorded 79% uptake with 0.02 M HCl activation washing out non-zeolitic impurities present in the original form as confirmed by SEM-EDS. The strong band at 1 341 cm⁻¹ for all the forms. This is characteristic band appears at 836 cm⁻¹ for all the forms. This is the quartz band (Al-Degea et al., 2004). The peak that appears at 753 cm⁻¹ for the original form of clinoptilolite appears at 759 cm⁻¹ for the activated zeolite. There is a peak that appears at 686 cm⁻¹ for the original form while for the acid-activated form it appears at 635 cm⁻¹. This shift could be attributed to the action of the acid.

It has been documented that acid treatment of natural clinoptilolite improves its adsorbent properties (Korkuna et al., 2006; Inglezakiz et al., 2001; Athanasiadis et al., 2005). This is due to de-catination, de-alumination and the dissolution of amorphous silica fragments blocking the channels. A study by Korkuna et al. (2006) also revealed that there is a change in the clinoptilolite structure after acid treatment with dilute acid activations accounting for improved removal capacity of the clinoptilolites. Studies by Vasylicheko et al. (1999) and Hernandez (2000) confirm findings in this study with respect to the effect of acid conditioning of natural clinoptilolite.

Conclusions

Relatively speaking, it was easier to remove Cu²⁺ than Co²⁺ from the non-mixed solutions. Uptakes of 79% for Cu²⁺ and 63% for Co²⁺ were obtained. The removal efficiency of the metals by the zeolite from dilute solutions was higher than from concentrated solutions for both non-mixed and mixed solutions. Clinoptilolite activated with 0.02M HCl was the best performing zeolite for both Co²⁺ and Cu²⁺ removal in non-mixed solutions. Uptakes of 79% and 63% for Cu²⁺ and Co²⁺ were recorded with 0.02 M and 0.04M HCl activation, respectively.
